The bowels should be kept regular; this can be done most conveniently by means of light oxide of magnesia, which should be given after each meal, as it helps to neutralise the free acid in the gastric contents. The most convenient way to take it is in a fluid preparation, containing 5 grains of magnesia to 60 minims, from 30 to 240 minims being required as a dose. If the magnesia is insufficient to control the constipation, a tablespoonful of liquid paraffin may be given after one or more meals.

The patient should continue to take a tablespoonful of olive oil half an hour before meals. He should for a time take a teaspoonful of magnesium trisilicate after meals and subsequently have some always available so as to be able to take just enough to keep himself perfectly comfortable at the slightest suspicion of heartburn or gastric discomfort. He should be warned of the danger of recurrence, and should be told to go to bed on a milk diet at the first indication of a return of symptoms. If he does this, treatment for a few days is often sufficient to ward off an attack. If, on the other hand, he waits until the symptoms become fully developed, a prolonged stay in bed will be required. The strict ulcer treatment and the post-ulcer regime can be summarised as follows.

Strict Ulcer Treatment

The patient should remain in bed on the strict treatment without alteration until healing is complete

Every other hour from 8 a.m. to 10 p.m. 5 oz. of milk. This can be warm or cold and may be flavoured with tea.

Every other hour from 9 a.m. to 9 p.m., a 5-oz feed which may be made of any of the following:

(*a*) Arrowroot, farola, Benger, junket, custard. These can be made more appetising by the addition of a little red currant, apple or other fruit jelly, and the junket may be flavoured with chocolate.

(*b*) At least two should consist of a thick soup or semi-solid purée of potato, artichoke, cauliflower or parsnip.

During the night the patient should have citrated milk by his bedside, so that whenever he wakes he can take a feed.

A rusk with butter should be eaten with three feeds. A "coddled egg" and some thin bread and butter may be taken once or twice a day by patients who can be relied upon to chew them thoroughly.

Small quantities of water may be drunk between feeds. An ounce of strained orange juice should be taken with three of the drinks.

One oz. of cream should be added to the 11 a.m., 1 p.m. and 5 p.m. feeds, and ½ oz. of olive oil should be taken before the 9 a.m., 2 p.m. and 7 p.m. feeds.

Ten grs. of sodium citrate in a teaspoonful of water should be added to each milk feed.

Sixty minims of atropine mixture (atropine sulphate, gr. $\frac{1}{150}$, in min. 60 water) before the 8 a.m. and 3 p.m. feeds, and 120 minims before the 10 p.m. feed. The dose should be increased by 10 minims every day until an unpleasant degree of dryness of the mouth or paralysis of accommodation occurs; the dose should then be reduced to that of the previous day.

Thirty grains of magnesium trisilicate half-way between feeds and 60 grains last thing at night.

Wash the mouth out after each feed.

No smoking during the strict treatment.

The patient should be weighed once a week. If he is too thin and has not gained weight, as often happens with gastric ulcers, the feeds should be increased to 6 or 7 oz. If he is too fat and has not lost weight, as sometimes happens with duodenal ulcers, the feeds should be reduced to 4 or 3 oz.

Post-Ulcer Regime

To be followed permanently

Avoid alcohol except, if desired later on, a small quantity of light wine or diluted whisky at meals. Avoid effervescing drinks and coffee.

Avoid all pips and skins of fruit (raw, cooked or in jam, and raisins and lemon-peel in puddings and cake), nuts and all unripe fruit. An orange may be sucked but not eaten. Currants, raisins and figs are particularly undesirable.

Avoid all raw vegetables, whether taken alone (celery, tomatoes, cucumber, water-cress) or in pickles and salad; green vegetables must be passed through a sieve and mixed with butter in the form of a purée. Avoid spinach. Porridge is only allowed if made with the finest oatmeal.

Avoid vinegar, lemon juice, sour fruit; pepper, mustard, curry, chutney, excess of salt; new bread; cooked cheese; fried fish; tough meat; pork; high game; clear and thick meat soup. During the first six months after recovery from an ulcer it is best to avoid meat altogether.

Take plenty of butter and cream, and a tablespoonful of olive oil before each meal.

Eat slowly and chew very thoroughly. An adequate time should be allowed for meals; rest for at least a quarter of an hour before and after meals. Meals must be punctual.

Do not smoke excessively; cigarettes should have an absorbent plug in their mouth-piece. No smoking at all if any indigestion.

A meal or feed (milk, plain biscuit or chocolate) should be taken at intervals of not more than 2 hours from waking to retiring, and again if awake during the night.

A teaspoonful or two tablets of magnesium trisilicate should be taken an hour after meals and also whenever the slightest indigestion or heartburn is felt. If the curve of acidity is very high, the atropine mixture should be taken before meals.

The bowels should be kept regular by means of magnesia and liquid paraffin, but no other aperients should be taken.

Have your teeth attended to regularly every six months.

Take no drugs in tablet form. Avoid aspirin in any form.

Special care should be taken to avoid chills. If you get a cold, sore throat, influenza or other infection, remain in bed on a very light diet until you have completely recovered.

If you have the slightest return of symptoms, go to bed on a strict diet. Consult your doctor and do not wait for the symptoms to get serious.

Surgical Treatment

An operation should be advised under the following circumstances.

1. At the earliest moment after a perforation.
2. For pyloric obstruction without active ulceration.
3. For pyloric obstruction with active ulceration, if it is still present after three weeks of rest, dieting and evacuation every night.
4. For a gastric ulcer causing organic hour-glass contraction sufficiently severe to produce 3-hour stasis in the proximal segment. This is very rare.
5. When the symptoms recur after one or more courses of thorough medical treatment followed by adequate after-treatment; the number of such courses which may be tried depends upon such circumstances as the social position, occupation and place of residence of the patient. Thus the better the social position of the patient, the less strenuous his occupation and the less important occasional absences from business, and the warmer and more equable the climate, the less urgent is the necessity for operation. In my experience recurrence after medical treatment is very unusual in the absence of pyloric obstruction if the ulcer has once completely healed, the teeth are in good condition and the after-treatment is conscientiously carried out. The results of surgery are least satisfactory when evacuation is rapid and in young people and are best when the stomach empties slowly and after the age of 50, especially in women.
6. As it is rare for death to occur from hæmorrhage, an operation is hardly ever indicated. It is required only when severe hæmorrhage recurs more than once whilst the patient is under the strictest treatment, especially in patients past middle age with sclerotic blood vessels and a long history of ulcer. An attempt should then be made to excise the ulcer or, if this is impossible, to ligature the bleeding point; failing this also, a series of sutures should be tied round the ulcer so as to cut off as much as possible of its blood supply. Gastro-jejunostomy alone is quite useless unless pyloric obstruction is present. The patient should be given a continuous transfusion to bring the hæmoglobin up to 80 per cent. immediately before the operation.
7. When for any reason, such as the persistence of pain or of occult blood in the stools whilst under strict treatment, it appears possible that a growth of the stomach is present, the abdomen should be explored, and unless a growth can be excluded with certainty, partial gastrectomy should be performed.
8. As malignant degeneration occurs about ten times more frequently in the comparatively rare prepyloric than in the common lesser curvature ulcers, and as it is often impossible with the X-rays to distinguish a simple ulcer from an early malignant ulcer in the prepyloric region, partial gastrectomy should be performed in all cases of prepyloric ulcer which do not rapidly respond to medical treatment, but not a gastro-jejunostomy, as it is im-

possible to exclude early malignant changes even by inspection and palpation during the operation.

Partial gastrectomy is the only satisfactory operation for a gastric ulcer, wherever it is situated. Gastro-jejunostomy is the best operation for duodenal ulcer producing obstruction. Partial gastrectomy has recently become popular as treatment for duodenal ulcer. But it leads to achlorhydria in only 50 per cent. of cases in contrast with almost 100 per cent. when performed for gastric ulcer, and in my experience it is no more uncommon for an anastomotic ulcer to develop in the remaining 50 per cent., in which hyperchlorhydria persists, than after gastro-jejunostomy. As the mortality of the operation is considerably higher than for the latter, and as further surgery is almost out of the question when an anastomotic ulcer develops after partial gastrectomy, I am convinced that the operation should not be performed for duodenal ulcer.

After an operation for gastric or duodenal ulcer the patient should follow exactly the same after-treatment as after medical treatment, or various ill-results, the most serious of which is the production of a gastro-jejunal or jejunal ulcer, may ensue.

Post-Operative Gastro-Jejunitis and Acute and Chronic Gastro-Jejunal and Jejunal Ulcer; Gastro-Colic Fistula

Ætiology.—The incidence of gastro-jejunal ulcer and jejunal ulcer after gastric operations depends upon the acidity of the gastric contents following the operation. It is consequently much more common after gastro-jejunostomy performed for duodenal ulcer, occurring in at least 10 per cent. of cases, than when performed for gastric ulcer, and it never follows operations for carcinoma. It may occur after partial gastrectomy, especially when performed for duodenal ulcer or gastro-jejunal ulcer, as hyperchlorhydria persists in about 50 per cent. of cases. It is especially likely to occur if septic foci are present in the mouth or naso-pharynx and if the patient does not follow a strict dietetic regime. In 20 per cent. of cases the anastomotic ulcer develops immediately after the operation and in the majority within 2 years, but I have known one develop after 21 years of freedom from symptoms.

The condition begins with inflammation of the anastomotic area, the neighbouring gastric mucous membrane, and the first inch of the distal limb of jejunum. Acute ulcers, which may cause severe hæmorrhage or perforate, follow; these may heal spontaneously or develop into chronic ulcers. Gastro-jejunal and jejunal ulcers are of equal frequency.

Symptoms.—The indigestion which follows gastro-jejunostomy is due in a large proportion of cases to an anastomotic ulcer. The commonest symptom is pain, which comes on soon after meals in contrast with its comparatively late onset before the operation, and it is generally situated to the left of the umbilicus instead of at a higher level and in the middle line or to the right. Hæmatemesis, which is often the only symptom, occurs in about 50 per cent. of cases, and occult blood is always present in the stools. Perforation may also occur without warning. In about 5 per cent. of cases the ulcer becomes adherent to the colon, and a gastro-colic, gastro-jejuno-colic or jejuno-colic fistula develops. This may at first cause little or no change in the symptoms, but sooner or later diarrhœa, which is occasionally

fatty, and vomiting of fæculent material or eructation of foul gas occur. In rare cases the proximal part of the colon becomes obstructed and severe pain and distension from accumulated fæces results.

A "niche," corresponding with an ulcer crater, can generally be recognised with the X-rays when a chronic ulcer is present, but in the frequent cases in which recurrent acute ulcers develop nothing abnormal can be seen. Gastroscopy has demonstrated the frequency of acute inflammation with or without erosions in the mucous membrane on the gastric side of the anastomosis in cases in which nothing abnormal is revealed with the X-rays, especially when hæmorrhage is the only symptom. Direct pressure over the stoma or the jejunum just beyond it often gives rise to pain. Free acid is invariably found after a fractional test-meal if care is taken not to allow the tube to pass through the stoma; in the majority of cases there is hyperchlorhydria. An opaque meal can sometimes be seen to pass direct into the colon if a fistula has developed; in other cases the fistula can be recognised only after an opaque enema, when some of the barium is seen to pass direct from the colon into the stomach.

Treatment.—Prolonged treatment of exactly the same kind as that described for gastric and duodenal ulcer generally results in healing. The hypertrophic gastritis, which often occurs around the stoma in the absence of a chronic ulcer and which is a common cause of recurrent hæmorrhage, responds to lavage with silver nitrate, as described on page 586. When medical treatment fails or when the symptoms recur in spite of following a careful regime after healing, the whole of the anastomotic area should be excised and the parts restored to their original anatomy unless pyloric or duodenal obstruction is present, in which case a partial gastrectomy must be performed. It should be remembered that no sign of the ulcer may be visible on external examination, and that it is useless merely to divide any adhesions which may be found, as they are never responsible for the symptoms.

TUBERCULOSIS OF THE STOMACH

Tuberculosis of the stomach is very rare. In miliary tuberculosis the mucous membrane may be involved, but no symptoms are produced. In advanced pulmonary tuberculosis a tuberculous ulcer may form, generally near the pylorus. The symptoms are indistinguishable from the dyspepsia common in such cases, unless hæmatemesis occurs; this may, however, be due to the presence of a simple ulcer. I have seen one case of chronic gastric ulcer and one of carcinoma, in which microscopical examination of the specimen removed at operation showed that secondary tuberculous infection had taken place. Both were associated with achlorhydria and had no distinctive symptoms, and the primary infection which was presumably present in the lungs was completely latent.

SYPHILIS OF THE STOMACH

Ætiology.—Syphilis of the stomach is apparently not uncommon in America and some Continental countries, but it is certainly very rare in

England. It occurs in males twice as frequently as in females. Its incidence is greatest between the ages of 30 and 40, and it may develop any time between 4 and 40 years after infection.

Pathology.—Characteristic gummatous infiltration of the walls of the stomach, especially the pyloric end, has been found in specimens excised at operation and much less frequently at autopsy. In at least two post-mortem specimens spirochætes were discovered.

Symptoms.—Epigastric pain generally occurs immediately after meals; less frequently it is delayed as in ulcer. Fluids and small meals give some relief. Vomiting is common, but nausea, anorexia and anæmia are rare. The symptoms become steadily worse with increasing loss of weight and strength. Hæmorrhage is very rare, and occult blood is only occasionally found in the stools. Achlorhydria is present in 85 per cent. of cases and hypochlorhydria in most of the remainder. The lesion is most frequently prepyloric, but pyloric incompetence owing to rigidity of the outlet of the stomach is as common as pyloric obstruction, and less frequently an hour-glass contraction is present. A tumour is only occasionally palpable. In 25 per cent. of cases other clinical signs of syphilis are found.

The X-rays generally reveal a local or diffuse involvement of the walls, which lead to stiffening, diminished mobility and abnormal peristalsis. The stomach is generally small. Less frequently there is a filling defect and very rarely a niche.

Diagnosis.—The possibility of syphilis should always be considered when symptoms suggestive of cancer are present; even if there is no history or other evidence of syphilis the Wassermann reaction should be tested. The diagnosis would be confirmed by the rapid improvement with anti-syphilitic treatment in spite of the failure of other measures. In one case typical symptoms of duodenal ulcer were present, but no improvement had followed prolonged treatment of the usual kind. Achlorhydria was then discovered to be present instead of the hyperchlorhydria of duodenal ulcer, and there was no duodenal deformity; the Wassermann reaction was positive, and rapid recovery with restoration of gastric secretion followed anti-syphilitic treatment.

Treatment.—The usual treatment for syphilis should be given; it is generally very successful. In late cases a short-circuiting operation may be required for pyloric obstruction caused by cicatricial contraction if anti-syphilitic treatment has failed to give relief.

CARCINOMA OF THE STOMACH

Ætiology and Pathogenesis.—Carcinoma of the stomach is commonest between the ages of 45 and 65; but, when allowance is made for the number of people living at each age, it is found that there is a steady rise in the incidence throughout adult life. This is due to the fact that the exciting causes act very slowly and require a considerable fraction of the normal span of life before they become effective.

Carcinoma never develops in a normal stomach. Clinical and pathological evidence shows that it occasionally develops from chronic gastric ulcer; this happens much more frequently in the relatively rare prepyloric ulcer than in the common lesser curvature ulcer. In about 6 per cent. of

chronic ulcers excised by operation, which appear innocent to the naked eye, small areas are found in the margin which show microscopical evidence of malignant degeneration, and in about 16 per cent. of cases of obvious carcinoma there is pathological or clinical evidence that the disease followed a simple chronic ulcer (Stewart). Cases of *ulcer-cancer* generally give a history of ulcer and have free hydrochloric acid in the gastric contents. I believe that the remaining cases of carcinoma of the stomach, most of which are associated with achlorhydria or extreme hypochlorhydria, are a sequel of chronic gastritis, which was either latent or caused comparatively trivial symptoms (*gastritis-cancer*). Numerous cases have been observed in which carcinoma developed in a patient who was known to have achlorhydric gastritis, associated with digestive symptoms, pernicious anæmia or subacute combined degeneration of the cord, months or years before the first symptom of carcinoma appeared. The achlorhydria is not a result of the carcinoma, but of the primary gastritis which is always found involving the part of the mucous membrane not attacked by the growth.

For the development of cancer two intrinsic factors, the individual constitutional susceptibility to cancer and a constitutional organ inferiority (the hypersthenic and hyposthenic gastric diatheses in the case of the stomach) are essential, but until an extrinsic factor in the form of chronic irritation is present the organ will escape disease. The first factor—the constitutional susceptibility to cancer—is constant, as the total incidence of cancer is approximately the same in both sexes, all social classes and all countries. But the incidence of carcinoma of the stomach differs greatly in the two sexes and in different classes and nations. It is more common in men than women, because so many women susceptible to cancer develop it in the breast or uterus, but the incidence in the stomach compared with the remaining organs is the same in men and women. Clinical and post-mortem statistics show that the stomach accounts for only 30 per cent. of deaths from cancer of the alimentary canal in England compared with 65 per cent. in Holland and Sweden, and cancer of the stomach occurs in England with double the frequency in the poor compared with the well-to-do, although the relative frequency of cancer in other organs is approximately the same in all countries and in all classes. These differences are almost certainly due to the third factor (extrinsic irritation) and not the second (organ inferiority).

Carcinoma involves the pylorus in 66 per cent. of cases. The fundus, especially in the neighbourhood of the cardia, and the lesser curvature are next most frequently involved.

Symptoms.—When an individual above the age of 40, who has hitherto had a good digestion, suddenly begins to suffer from gastric symptoms, the possibility of cancer should always be considered. The most common symptom is epigastric discomfort or pain immediately or soon after meals. After a time the pain, which is generally dull and distressing, but not very acute, becomes continuous, but it is still aggravated by meals. In a small proportion of cases the pain begins 2 or 3 hours after meals and is relieved by food, thus simulating duodenal ulcer, but there are never spontaneous remissions of symptoms, and in these cases achlorhydria is always present. At an early stage the appetite diminishes, the patient having a special repugnance for meat. This may be the first symptom in achlorhydric cases, but in ulcer-cancer the appetite is often maintained for a time. The anorexia may be

associated with nausea, which can also occur independently, occasionally as the earliest symptom. In about one-fifth of the cases there is a long history of symptoms suggestive of gastric ulcer, the pain having recently become more severe and continuous instead of intermittent.

Though anæmia is often present, the blood picture may remain normal even in very extensive and inoperable growths with much occult blood in the stools. The anæmia is partly due to constant oozing from the ulcerated growth, but this has comparatively little effect unless actual hæmatemesis or melæna occurs; anæmia of this kind can be overcome by treatment with iron and, in severe cases, repeated transfusions. It is often of the simple achlorhydric type, which responds rapidly to treatment with large doses of iron, and occasionally it is Addisonian and responds to treatment with liver in spite of the presence of a growth. Flatulence is commonly present, the gas brought up being at first odourless, but subsequently foul. Vomiting is generally present sooner or later. In cancer of the cardiac end of the stomach dysphagia with regurgitation of food immediately after swallowing occurs, the symptoms being indistinguishable from those of a growth of the lower end of the œsophagus. Vomiting is commonly preceded by pain and nausea, both of which it temporarily relieves, but less completely than in gastric ulcer. The vomited matter contains blood more often than in gastric ulcer: it often has the appearance of "coffee grounds." Hæmatemesis is rare, but in exceptional cases may be the earliest symptom. In a very large proportion of cases blood constantly oozes from the surface of the growth, so that one or more of the specimens obtained with a fractional test-meal may be obviously blood-stained, and all are likely to contain occult blood. The oozing is unaffected by diet, so that occult blood is present in every stool examined, however carefully the patient is dieted. The growth sooner or later involves the pylorus in two-thirds of all cases; the special symptoms then present are described in the article on pyloric obstruction.

The patient rapidly loses strength and weight, the emaciation being more than can be accounted for by the vomiting and diminished intake of food. In the late stages the disappearance of subcutaneous fat, loss of elasticity of the skin, œdema of the abdominal wall, back and ankles, and anæmia give the patient a characteristic cachectic appearance.

In the earlier stages nothing abnormal is found on abdominal palpation; but sooner or later a hard, moderately tender tumour is generally felt. It is often most easily palpable when the stomach is empty, but occasionally only becomes obvious after meals. When the fundus or body is involved the tumour is felt descending from under the left costal margin. In carcinoma of the lesser curvature and pylorus the tumour lies across the upper part of the epigastrium.

The X-rays often show an irregular filling defect in the outline of the stomach, which coincides with the tumour if one is palpable, and often involves the greater curvature. The normal progress of the peristaltic waves is interrupted, sometimes before any obvious deformity is present. The first radiological sign may be irregularity in the arrangement of the folds of mucous membrane seen in a radiograph taken after swallowing one or two mouthfuls of a suspension of barium sulphate. In carcinoma of the fundus, the arc formed by the gas under the diaphragm is irregular in shape and reduced in size, and the growth itself may be faintly visible through the gas bubble.

If there is the slightest reason to suspect cancer a fractional test-meal should be given. The resting-juice often contains pus cells in excess of the leucocytes present in a specimen of spittle obtained at the same time, and even if the specimen is not obviously blood-stained, red corpuscles are generally found on microscopical examination. In 60 per cent. of cases complete achlorhydria is present, and in at least another 20 per cent. there is hypochlorhydria; in most cases secondary to ulcer free acid is present, sometimes actually in excess. If pyloric obstruction and achlorhydria are present, but not otherwise, the resting-juice generally contains lactic acid. It is, however, absent if the stomach is washed out thoroughly the previous evening. It is thus a product of the decomposition of stagnating food and is not a secretion of the growth. Moreover, the lactic acid is the inactive variety, and therefore of fermentative and not animal origin. Consequently lactic acid, though most often found in pyloric carcinoma, may also be present in other conditions, such as migraine, if achlorhydria and gastric stasis are present together.

Secondary deposits frequently occur in the liver and in 5 per cent. of cases in both ovaries, and the symptoms they give rise to may be the most prominent clinical manifestation. Direct spread to the peritoneum and omentum is common, and irregular abdominal masses are often palpable; ascites may occur as a result of the malignant peritonitis. A small gland just beneath the insertion of the left sterno-mastoid muscle is generally attacked before any other cervical glands, and less frequently deposits occur in the inguinal glands. The growth may spread along the urachus to involve the umbilicus, where a hard nodular mass can be felt. A rectal examination should always be made, as a deposit is not infrequently present in the recto-vesical or recto-vaginal pouch at a comparatively early stage.

Perforation may occur, general peritonitis being usually prevented by the presence of old adhesions, so that a local abscess forms; less frequently the colon becomes involved and a gastro-colic fistula results, the patient then rapidly dying from emaciation due to constant fæcal vomiting and severe diarrhœa.

Other terminal complications are suppurative gastritis, pylephlebitis, suppurative parotitis, thrombo-phlebitis migrans, septic pneumonia, empyema and infective endocarditis.

Diagnosis.—Apart from the history and the discovery of a tumour, the X-ray examination is the most important means of distinguishing a growth from other gastric disorders. Occult blood is present in the stools for prolonged periods in many cases of ulcer, but achlorhydria is very rare; and in the few cases of very chronic lesser curvature ulcers in which there is no free acid, it generally reappears if the meal is repeated after washing out the stomach. Moreover, the characteristic X-ray appearance of an ulcer crater is quite different from the appearance produced by a growth. In gastric ulcer the pain begins only at an interval after meals, and if present when food is taken it is temporarily relieved, whereas in cancer the pain generally begins directly after meals and is rarely relieved by food. In the group of cases in which duodenal ulcer is simulated, the absence of periods of freedom from symptoms, the presence of achlorhydria and the X-ray appearance should prevent a mistake in diagnosis. Pernicious anæmia may closely simulate a growth of the stomach; the presence of occult blood in the stools

is distinctive of the latter and rarely occurs in the former; the megalocytosis, high colour index, and positive indirect but negative direct van den Bergh's test of pernicious anæmia are in striking contrast with the absence of megalocytes, normal or low colour index and negative van den Bergh's test of cancer, however severe the anæmia is. It should, however, be remembered that an extensive growth may be present even with a hæmoglobin percentage of 100, and that in rare cases pernicious anæmia may be associated with carcinoma of the stomach.

Prognosis.—The average duration of life after the appearance of the first symptoms is a year. Temporary improvement and considerable gain in weight may occur as a result of rest and careful dieting. Death is most frequently due to exhaustion; in other cases it results from one of the complications already mentioned.

Treatment.—Medical treatment is only palliative. In ulcer-cancer with free acid present, the post-ulcer regime (p. 595) with alkalis may keep the patient quite comfortable. In gastritis-cancer with achlorhydria a gastritis diet should be given; occasional lavage may give much relief, and an acid mixture may improve the appetite. Analgesic drugs, especially aspirin, are generally sufficient to control the pain, and it is only rarely necessary to give morphine, but when nothing else gives relief there should be no hesitation in giving very large doses.

An operation should be performed in all cases in which there is no evidence of secondary deposits or involvement of glands beyond those in the immediate neighbourhood of the stomach, unless it is found impossible to improve the patient's condition sufficiently to hold out any hope of success. If anæmia is present it should be treated before operation with large doses of iron, and, if necessary, repeated transfusions until the hæmoglobin percentage is 80. When the pylorus is obstructed, the stomach should be washed out every morning and evening for a week before operation and large quantities of saline solution given by rectum. With proper preparation and bold and skilful surgery many apparently inoperable tumours can be completely removed. If secondary deposits make a radical operation impossible in a case of pyloric carcinoma, much relief follows gastro-jejunostomy. Small nodules in the liver are not a contra-indication of partial gastrectomy, as they may grow very slowly so that the patient remains quite comfortable for many months after the operation.

HOUR-GLASS STOMACH

A gastric ulcer situated on the lesser curvature may give rise to spasm of the corresponding segment of circular muscle fibres, which leads to a depression or "incisura" on the greater curvature, like a finger pointing at the "niche" on the lesser curvature. The degree of spasm varies with the activity of the ulcer, but a slight spasm may persist after healing is complete. It never gives rise to sufficient obstruction to cause stasis or increased peristalsis in the proximal segment. It may disappear on vigorous massage or after strongly contracting the abdominal muscles and sometimes, but not always, after the administration of atropine. A less persistent spasm may occur as a reflex result of duodenal ulcer, disease of the gall-bladder and appendicitis.

Cicatrisation of a very chronic gastric ulcer may produce an hour-glass constriction. This hardly ever occurs in men, the large majority of cases being in women with such a high threshold of sensibility to pain that, though they may have had an ulcer for 20 or 30 years, they have never suffered from indigestion of sufficient severity to raise a suspicion of the presence of organic disease. The frequency of hour-glass stomach has steadily diminished during the last 25 years and the condition is now rare, probably owing to earlier diagnosis and better medical treatment. In 50 per cent. of cases found *post mortem* the ulcer has healed completely and is replaced by a scar. The comparatively rapid healing of a lesser curvature ulcer by medical treatment, however large the ulcer may be, never results in an hour-glass stomach, a period of many years with alternating periods of activity and spontaneous healing being essential for its development. The obstruction caused by an hour-glass contraction with a still active ulcer is always exaggerated by the presence of spasm, so that the narrowing found at operation is often much less than would be suspected from the radiograph.

One of the two hour-glass stomachs I have seen in men was caused by a band passing from an ulcer on the lesser curvature to the omentum; the constriction disappeared when this was divided. Hour-glass constrictions caused by cancer and syphilis are extremely rare.

Symptoms.—In organic hour-glass stomach a history of comparatively slight indigestion occurring intermittently for many years, possibly with one or more hæmorrhages, can almost always be obtained. The symptoms are similar to those of pyloric obstruction due to ulcer, with the exception that the amount vomited is generally less, and greater relief is obtained on lying down. There is no visible peristalsis unless the proximal segment is unusually large. The X-rays are the only reliable method of diagnosis; the constriction can be seen whether the patient is standing or lying down, and in the former position the neck passes from a point above and to the right of the lowest part of the proximal segment. If an active ulcer is present, the niche produced by the crater is seen on the lesser curvature.

Treatment.—If no niche is present and the upper sac of the stomach is empty within 4 hours, the patient often keeps perfectly well by following the "post-ulcer regime" (p. 595). If the ulcer is still active, surgery is indicated. When the constriction is sufficiently narrow to produce definite stasis in the proximal sac, a gastro-gastrostomy should be performed. If this is impossible for technical reasons, or if there is little or no stasis in the proximal sac, a partial gastrectomy should be performed. As an hour-glass constriction is occasionally associated with pyloric obstruction, the condition of the pylorus should always be investigated in case a gastro-jejunostomy is required in addition to a gastro-gastrostomy.

PYLORIC OBSTRUCTION

Ætiology.—Pyloric obstruction may be organic and incurable or functional and curable. Organic obstruction of the pylorus or duodenal bulb is caused by the contraction of fibrous tissue formed during cicatrisation of an ulcer in its neighbourhood, 85 per cent. being duodenal and 15 per cent. prepyloric. Two-thirds of all cases of carcinoma of the stomach involve the pylorus.

Pyloric obstruction occasionally results from chronic gastritis: this may be due to (1) a generalised sclerosis of the mucosa, submucosa and muscular coats. (2) simple muscular hypertrophy; and (3) swelling of the mucosa alone. Syphilis is a rare cause of pyloric obstruction. In infants, obstruction may result from hypertrophy of the pyloric sphincter (p. 606).

External pressure very rarely causes pyloric obstruction, and simple adhesions between the pylorus and the neighbouring viscera do not as a rule interfere with the passage of food into the duodenum. In exceptional cases, however, cholecystitis may lead to such strong and extensive adhesions with the pylorus that a certain amount of obstruction results. Gastroptosis never causes pyloric obstruction (*vide* Visceroptosis, p. 746).

The œdema and congestion round an active duodenal or prepyloric ulcer may cause severe obstruction, which disappears when the ulcer heals as a result of treatment. In such cases the obstruction is exaggerated by the presence of achalasia or spasm of the sphincter, which may also occur with an ulcer on the lesser curvature and with cholecystitis.

Symptoms.—In the early stages attacks of severe pain may occur at varying intervals after meals owing to the violent peristalsis of the stomach in its attempt to overcome the obstruction. Later, nothing more than an unpleasant sense of fullness is experienced, especially after meals, but if frequent vomiting or treatment by lavage prevents the stomach from becoming much distended, attacks of pain are likely to persist. With an ordinary diet vomiting occurs regularly every day, but this characteristic symptom is less marked if the patient takes food which leaves little or no solid residue. The vomiting generally occurs at first in the afternoon or evening; but in the later stages, when dilatation has supervened, large quantities are vomited several times a day and often during the night. Articles of food may be brought up which have been eaten many hours or even days before. The odour is sour in non-malignant and rancid in malignant cases. Excessive fermentation and putrefaction may give rise to very offensive eructation, and in rare cases this is the first symptom noticed by the patient, especially, but not exclusively, in malignant obstruction. Wasting is progressive, and the tissues become abnormally dry and inelastic. The patient has generally little appetite, but complains of great thirst. The urine is scanty, and obstinate constipation occurs.

Pyloric obstruction occasionally gives rise to tetany and to symptoms simulating uræmia, but although there is a considerable rise in the blood urea the condition is caused by chlorine deficiency and alkalosis and not renal insufficiency.

In addition to the symptoms already enumerated, others depending upon the cause of the obstruction, such as ulcer or carcinoma, are of course also present.

Pyloric obstruction leads to distension of the stomach. The signs of this, together with the distinctions between the malignant and non-malignant cases, are considered in the section on the examination of the stomach.

Treatment.—The treatment of organic pyloric obstruction is surgical. It is useless to waste time in well-marked cases with lavage or other medical treatment, as the improvement which follows operation is immediate and progressive. The immediate mortality of the operation can, however, be greatly reduced by preliminary medical treatment for a few days. The stomach is completely emptied every night by Senoran's evacuator. Small

quantities of custard, junket and similar soft easily digestible foods, but no fluids, are given during the day, saline solution being given by rectum. By this means the tone of the stomach rapidly improves, and the danger of severe intoxication due to alkalosis is overcome.

When the obstruction is only partial and an active ulcer is present, the effect of medical treatment of the ulcer should be tried, as the obstruction is largely due to the surrounding inflammation, which disappears when the ulcer heals, and when healing is rapid the scar generally gives rise to no obstruction.

ARTHUR F. HURST.

CONGENITAL HYPERTROPHY OF THE PYLORUS

Synonym.—Hypertrophic Pyloric Stenosis.

Definition.—This is a disease of early life, formerly believed to be a rarity, but now recognised as of not uncommon occurrence. It consists essentially in a great thickening of the pylorus, leading to gastric stasis, with all the symptoms that result from such a condition.

Ætiology.—The pathogeny of the disease is still obscure. The theory that it is simply a congenital malformation is not in harmony with the clinical facts, and the most generally accepted view is that it results from an over-action of the pyloric sphincter, the consequence of a lack of co-ordination between the gastric and pyloric mechanisms. There is some reason to suppose that the Anglo-Saxon and Teutonic races are more affected by the disease than the Latin, but it is exceptional to get a history of other cases having occurred in the family. Boys are affected at least four times as often as girls, and in a remarkably high proportion the patient is the first child of the family.

Pathology.—The most striking change is an immense thickening of the pylorus, due to overgrowth of its circular muscle-fibres. The stomach is dilated, its muscular coat somewhat hypertrophied, and the mucous membrane in a state of catarrh. The other post-mortem appearances are those usually met with in inanition.

Symptoms.—The child has usually been born at full time, after a natural labour, and in the majority of cases has been breast fed. For a week or two or longer all goes well, and then vomiting sets in. The vomiting is "projectile" in character, the stomach contents being violently shot out. The vomit is usually larger in quantity than the last meal, and is often mixed with mucus; the presence of any blood in it is very rare. Meanwhile the child steadily loses weight, but does not look really ill, and maintains his strength and activity. The bowels are obstinately constipated, and the motions small and dark.

The most characteristic sign of the disease is the presence of *visible gastric peristalsis*. On inspection of the abdomen, waves of contraction can be seen sweeping across its upper part from left to right. Sometimes three such waves can be seen at once, each being about the size of a golf ball. The waves may not be seen unless the child has recently been fed, and if they are sluggish in appearing a little gentle stimulation below the left costal margin will often succeed in eliciting them. In most cases the overgrown

pylorus can be felt as a tumour by palpating deeply in the right hypochondrium. Sometimes, however, it is so tucked up under the liver that it cannot be felt.

Complications and Sequelæ.—The complication most to be dreaded is the supervention of an infective diarrhœa, which in these cases is apt to prove fatal. Some degree of biochemical disturbance is also apt to develop in severe cases. There are no sequelæ of the disease; if recovery takes place, it is complete and permanent, and indeed, many of the patients ultimately attain a degree of health and development beyond the average. The hypertrophy of the pylorus disappears.

Course.—The course of the disease varies greatly in different cases, and depends also to a large extent upon the treatment adopted, but unless operation is resorted to, it is always prolonged and recovery gradual. Even when the vomiting ceases, the weight may for long fail to rise, and the child may remain in a state of inanition, during which intercurrent disease may easily supervene.

Diagnosis.—This should not be difficult, provided the existence of the disease is remembered. The vomiting is distinguished from that of indigestion by its projectile character, and the coexistence of constipation is characteristic. The great diagnostic, however, is the presence of the visible peristalsis, and in the absence of this it is unwise to conclude that the disease is present. Many experts maintain that the pyloric tumour is palpable in the majority of cases. Mild cases of pyloric spasm may simulate true stenosis, but in these the symptoms are less severe, and definite waves of peristalsis are absent, The patient is often a girl. Stenosis of the duodenum from congenital malformation may simulate pyloric stenosis, but the symptoms in the duodenal cases date *from birth*, and bile is present in the vomited matter. An X-ray examination often helps in the diagnosis.

Prognosis.—It is very difficult to estimate the chances of recovery or the relative merits of different forms of treatment statistically. Much depends upon the severity of the particular case, but in general it may be stated that no case is so severe that recovery is impossible. Cases treated in private do much better than those seen in hospital.

Treatment.—There are two methods of treatment—medical and surgical. Medical treatment consists in washing out the stomach once or twice daily with normal saline, and carefully regulating the feeding. If breast milk is not available, a half-cream dried milk with the addition of dextrimaltose is the best substitute, and should be given in quantities of one or two ounces every 2 or 3 hours, depending upon the degree of vomiting. Atropine (3 to 9 drops of a 1 in 1000 solution of the sulphate, half an hour before each feed) is sometimes used with alleged benefit, and recently atropine methyl nitrate (eumydrin) (0·5 mgrm. given seven times daily half an hour before each feed) has been recommended as less toxic than atropine. If under this treatment the vomiting ceases, and the weight begins to rise, good and well. If not, or if the symptoms have set in early and with great severity, operation should be had recourse to, Rammstedt's plan of splitting the pylorus longitudinally being the procedure to be preferred.

ROBERT HUTCHISON.
ALAN MONCRIEFF.

ACUTE DILATATION OF THE STOMACH

Ætiology.—After operations, especially for acute abdominal conditions, and much less frequently in the course of acute infections, especially pneumonia, the stomach suddenly becomes greatly dilated owing to a complete loss of tone. The dilatation, which is often much aggravated by severe aerophagy, leads to complete obstruction of the duodenum by the mesentery at the point where the latter crosses it, and the dilatation then becomes extreme.

Symptoms.—The abdomen is very distended, large quantities of dark but not fæcal fluid are vomited, and the patient rapidly becomes very collapsed. "Black vomiting" after operations is almost always due to acute dilatation of the stomach, and not to the intestinal paralysis with which it is often associated.

Treatment.—The stomach should be kept empty by aspirating through a Ryle tube kept continuously in position, however ill the patient may be. Nothing should be given by the mouth, but saline solution should be injected continuously into a vein by the drip method. If recovery does not occur in two or three days, a jejunostomy should be performed, the patient being fed through the stoma till the stomach contracts to its normal size.

CHRONIC DUODENAL ILEUS

Ætiology and Pathogenesis.—Just before the duodenum turns upwards to end in the duodeno-jejunal flexure, it is crossed by the root of the mesentery. When the mesenteric vessels arise at a lower level than usual or the horizontal portion of the duodenum is situated unusually high, the slight anatomical variation from the average normal leads to some narrowing of the lumen of the duodenum where it is crossed. If the abdominal muscles are lax and the small intestines drop into the pelvis, they may be partially incarcerated there and the obstruction becomes more marked. In rare cases obstruction at the same point is caused by localised simple or tuberculous chronic peritonitis. The proximal part of the duodenum becomes dilated, and the violent peristalsis, which can be seen with the X-rays to give rise to backward and forward movements of its contents in its effort to pass the obstruction, results eventually in hypertrophy of its muscular coat.

Symptoms.—The condition generally gives rise to no symptoms and is discovered accidentally during a routine X-ray examination, but it may cause right-sided discomfort, which sometimes simulates duodenal ulcer or gall-bladder disease. Paroxysmal attacks of bilious vomiting may be the only symptom, especially in neurotic women. In rare cases it is the cause of cyclical vomiting in children, which persists into adult life; in one such case the consequent malnutrition led to dwarfism. The duodenal stasis may be a factor in the development of duodenal ulcer and of cholecystitis, when chronic ileus is present in an individual who is already predisposed to these conditions. An anterior duodenal ulcer associated with ileus is specially liable to perforate.

Treatment.—In most cases postural treatment gives complete relief. The patient should for a few weeks adopt a position for a quarter of an hour

every day in which the X-rays have shown that the obstruction is overcome. Lying on the right side or face downwards may be sufficient. In more severe cases the patient leans over the end of a couch with his head downwards, so that his trunk is perpendicular to the ground; this allows the incarcerated small intestine to drop out of the pelvis, and complete and permanent recovery may follow.

In my experience the results of duodeno-jejunostomy have been satisfactory only when the obstruction is sufficient to cause considerable duodenal stasis. In neurotic women with paroxysmal vomiting the symptoms almost invariably recur after a short interval of freedom.

When a duodenal ulcer is associated with duodenal ileus the danger of perforation calls for operation: gastro-jejunostomy is often successful, but it is sometimes followed by persistent vomiting, so that a duodeno-jejunostomy should probably be performed at the same time.

ARTHUR F. HURST.

DISEASES OF THE INTESTINES

INTRODUCTION

I. THE FUNCTIONAL DIVISIONS OF THE INTESTINES

i. *The small intestines.*—In the duodenum the food is mixed with the pancreatic juice, which is essential for the digestion of protein and fat, and with bile, which promotes the absorption of the products of fat digestion. In its passage through the small intestines the chyme is mixed with the succus entericus, which contains enterokinase, which activates the pancreatic ferments, and invertase, maltase and lactase. The chyme passes rapidly through the jejunum and greater part of the ileum, in the last 12 inches of which it remains for a considerable time. The terminal ileum indeed forms an "ileal stomach," in which the greater part of the digestion of protein, fat and carbohydrate takes place and the products of digestion are absorbed.

ii. *The proximal colon.*—Observations on patients with cæcal fistulæ show that about 350 g. of fluid chyme, containing 90 per cent. of water with very small quantities of sugar, fat, coagulable protein and of the soluble products of their digestion pass through the ileo-cæcal sphincter in a day. As the average weight of fæces is 135 g. and they contain only 75 per cent. of water with no sugar, coagulable protein or soluble products of digestion, it is clear that much water and all the soluble constituents of the chyme which reach the cæcum must be absorbed in the colon. This absorption takes place in the cæcum, ascending colon and proximal half of the transverse colon, which may therefore be regarded as the "colonic stomach."

iii. *The distal colon.*—The pelvic colon acts as a storehouse for fæces, to which they are conveyed through the transverse colon, the descending colon and the iliac colon when digestion in the colonic stomach is complete. Here they remain until the time for defæcation arrives.

iv. *The rectum.*—The rectum has the important function of maintaining

the regular evacuation of fæces. It is empty except immediately before defæcation, and the distension of its walls when fæces enter it is the normal stimulus to the defæcation reflex. The same stimulus produces the sensation which prompts the individual to perform the voluntary acts which help in the efficient performance of the reflex.

II. THE INTESTINAL MOVEMENTS

The movements of the intestines have two main objects: (1) mixing the food with the digestive juices and bringing them into contact with the mucous membrane which absorbs the products of digestion and water; and (2) propulsion of its contents from the duodenum to the rectum, and of the indigestible residue of the food from the rectum.

i. *The small intestines.*—In the small intestines peristalsis and segmentation take place simultaneously, the former with the object of propelling the chyme into the "ileal stomach," and the latter with the object of mixing the food with the digestive juices and exposing it to as large an area of mucous membrane as possible. In the jejunum and greater part of the ileum peristalsis is the predominating motor activity, but when the ileal stomach is reached it ceases almost completely and segmentation becomes extremely active. After a varying interval peristalsis becomes active again, and as the ileo-cæcal sphincter relaxes with the arrival of each peristaltic wave, the ileal stomach empties its contents into the cæcum.

ii. *The colon.*—When the colon is examined after an opaque meal it appears to be completely immobile. In spite of this, both segmentation and peristalsis occur under normal conditions, but their character differs considerably from the corresponding movements in the small intestine. Peristalsis occurs only in the form of "mass movements" about three times a day: a single very powerful peristaltic wave travels slowly along a considerable part or even the whole length of the colon, pushing in front of it most of the contents. Deep segmentation movements, which are too slow to be visible with the naked eye, can be recognised by comparing radiographs taken at three-minute intervals and often in those taken at intervals of a single minute. Segmentation is the result of the ceaseless activity of the muscularis mucosæ, the normal "haustration" of the colon seen with the X-rays being produced by projecting folds of mucous membrane. As a result of the continuous segmentation in the colonic stomach much of the water and all of the soluble constituents of the food and the products of their digestion which have escaped the small intestine are absorbed.

The chyme leaves the ileal stomach very slowly except during and immediately after meals, when as a result of a gastro-ileo-cæcal reflex frequent peristaltic waves pass down the terminal ileum to the ileo-cæcal sphincter, which opens widely as each wave reaches it. The chief stimulus to mass peristalsis of the colon is a gastro-colic reflex. On comparing these events it becomes clear that the ileal stomach passes its contents into the cæcum when it is necessary that it should be empty for the reception of the food coming down from the stomach after a meal, and that the colonic stomach similarly evacuates itself to leave room for the reception of the contents of the ileal stomach.

III. DEFÆCATION

During defæcation the contents of the pelvic colon, together with any fæces which may be present in the descending and iliac colon, pass into the rectum; the distension of the rectum causes it to contract as a whole just like the bladder and at the same time causes reflex relaxation of the sphincter ani, so that the contents of the rectum are evacuated. Simultaneously the contents of the cæcum and ascending colon pass into the transverse colon, whilst the contents of the latter pass into the pelvic colon.

Normal defæcation depends upon a conditioned reflex. The infant is taught at an early age to empty his bowels directly he is placed on a chamber. The act quickly becomes a purely reflex one, and it continues to be so when he grows older and the chamber is replaced by the seat in the w.c. Breakfast by itself gives rise to a simple gastro-colic reflex; sitting down on the familiar seat in the w.c. is, however, the starting-point of the more elaborate conditioned reflex, which produces the most efficient gastro-colic reflex of the day, in which the whole colon from the cæcum to the rectum takes part. In the healthy adult defæcation remains to a great extent a conditioned reflex. It is enough to sit down in the accustomed place, perhaps with a pipe and a newspaper, for the reflex to begin, often without the "call to defæcate"—the perineal sensation produced by the entry of fæces into the rectum, and without the voluntary stimulus produced by the increased intra-abdominal pressure caused by descent of the diaphragm and contraction of the abdominal muscles, though these, together with the final contraction of the levator ani muscles, are always brought into action to help in the complete expulsion of the fæces.

Failure to open the bowels on the first day of a holiday is not due, as is popularly supposed, to the "hard water" of the locality, deficient exercise in a train or on board ship, but to the unfamiliar w.c. and perhaps the unusual hour of getting up—or the absence of getting-up, such small changes being enough to upset for the moment the delicately adjusted conditioned reflex.

EXAMINATION OF THE INTESTINES

SIZE, SHAPE AND POSITION OF THE COLON

The cæcum and iliac colon are the only parts of the bowel which are always palpable under normal conditions. In very thin individuals and in patients with very lax abdominal muscles the whole colon except the splenic flexure and the pelvic colon can often be felt. Apart from these conditions the colon may become palpable when in a state of spasm or when filled with fæces, and tumours involving it can often be recognised by abdominal examination. In all intestinal cases a rectal examination must be made; by this means not only the rectum but also part of the pelvic colon can be palpated. For a thorough investigation of the size, shape and position of the whole colon in the erect as well as the horizontal postures an X-ray examination

after a barium meal is essential. The pelvic colon, and less frequently the descending and iliac colon, cannot always be seen satisfactorily, as they may be full only in the early morning, and defæcation empties them completely before it is convenient to make an X-ray examination. In such cases a barium enema renders all parts of the colon easily visible; the artificial distension produces a considerable amount of distortion, the error due to which can be overcome by making an additional examination after most of the fluid has been allowed to escape.

MOTOR FUNCTIONS

(*a*) PALPATION.—In every case of intestinal disorder an abdominal and rectal examination should be made. No medicine or enema should be given during the preceding 24 hours, but before this the colon should be emptied by whatever means the patient is in the habit of using. The quantity of fæces present in each part of the colon varies greatly according to the time at which meals are taken and defæcation occurs. With a normal individual whose bowels are satisfactorily opened after breakfast the whole of the colon is empty during the greater part of the morning, though a thin layer of soft fæces may cover the wall of the cæcum and perhaps the ascending colon and so render them partially opaque to the X-rays if a barium meal was taken 24 hours earlier, and a small quantity of semi-solid fæces may be present in the distal part of the transverse colon. Between 3 and 4 hours after breakfast the cæcum begins to fill; the filling becomes much more rapid after lunch, so that in a short time the ascending colon also becomes filled. During the rest of the day palpation shows the cæcum and ascending colon, and often the proximal part of the transverse colon, to be filled with soft fæces; as a rule this can be recognised much more easily in the part of the colon in the right iliac fossa, owing to the solid background it affords than in the more distal part. The resonant note which is generally obtained on percussion over the right half of the colon in the morning is replaced by a dull note in the afternoon.

In the early morning the rectum is empty, but the pelvic colon can be felt through the anterior rectal wall to be filled with solid scybala, which sometimes extend upwards into the iliac and the descending colon. On getting up, but often only after breakfast, the pelvic colon empties some of its contents into the rectum, giving rise to the "call to defæcate"; from this moment until defæcation has occurred is the only time in the day in which the rectum of a normal individual is filled with fæces. At all other times it is completely empty, and a proctoscope shows that there is not even a trace of fæces adherent to the mucous membrane. In defæcation the whole of the colon beyond the splenic flexure empties itself. Consequently the descending iliac and pelvic colon are empty during the whole morning, except that fæces may be conveyed during defæcation from the transverse colon into the lower part of the pelvic colon, and more may arrive from the proximal colon with the mass peristalsis occurring after lunch. Apart from this, the pelvic colon is generally empty or almost empty until after tea or more commonly after dinner, when another wave of mass peristalsis fills it with the contents of the colon from the neighbourhood of the hepatic flexure and the proximal half of the transverse colon.

The details of the movements vary greatly in different individuals, but the average conditions just described show how greatly the fullness of the different parts of the colon varies with the time of day, and how unjustifiable, for example, it is to diagnose cæcal and ascending colon stasis because these parts of the colon are full of fæces when examined in the afternoon.

If the rectum is full of fæces and the patient has no desire to defæcate, dyschezia can be diagnosed. If the fæces are soft it is clear that there can have been no delay in the passage to the rectum, such as is likely to have occurred if it contains hard and dry scybala. When the rectum is empty but the pelvic colon can be felt through the anterior rectal wall to contain scybala, the form of dyschezia which is due to inability of the pelvic colon to empty its contents into the rectum is present, but this can be diagnosed with certainty only if the patient has made an effort to open his bowels after breakfast and the examination is made before lunch. In severe cases hard scybala may also be felt in the iliac and perhaps the descending colon.

A full cæcum and ascending colon are of significance only if the examination is made within three hours of breakfast; even then primary right-sided stasis can be diagnosed only if the rectum and pelvic colon are empty.

(*b*) The Charcoal Method.—By giving two or three charcoal lozenges with some food 8 hours after defæcation and observing after what interval black fæces are passed, the total time taken in their passage through the alimentary canal can be ascertained. If, for example, a patient's bowels have been opened at 8 a.m., charcoal should be given at 4 p.m. the same day. If some of the charcoal is not passed at latest the second morning after being taken, the patient must be regarded as constipated. The method has, however, the great disadvantage of giving no indication as to the part of the bowel in which stasis occurs.

(*c*) X-ray Examination.—i. *Opaque meal.*—The only reliable means of determining whether a patient is suffering from chronic intestinal stasis, and of ascertaining exactly what parts of the alimentary canal are at fault, is a series of examinations with the X-rays. Examination with the fluorescent screen gives more information than is obtainable from radiographs. If the bowels have not been spontaneously opened the morning before the opaque meal is to be taken, an enema should be given in the evening. It is very important to discontinue the use of all aperients for at least 48 hours before the first examination, as the intestinal functions might otherwise be observed whilst still under their influence instead of under natural conditions. No aperients and no enemata should be used till the examination is finished, but the patient should make an attempt each morning to open his bowels naturally. If the attempt is successful, the stools should be examined to ascertain whether any of the barium has been evacuated. The patient should follow his usual occupations and take his ordinary diet. An examination should be made in the morning and evening of each day until all or most of the barium has been passed in the fæces or has reached the rectum.

ii. *Opaque enema.*—Although an opaque meal is the best means of obtaining information of the motor functions of the colon, an opaque enema generally gives earlier and more exact information concerning the possible presence of a stricture, especially in the iliac and pelvic colon, which often cannot be satisfactorily examined by the former method. A suspension is

made by adding 8 oz. of barium sulphate and 4 oz. of kaolin to a pint and a half of water. The patient lies on his back, and the fluid is run in from a container at a pressure of between 2 and 3 feet through a valveless Higginson's syringe connected with a rubber tube introduced just within the rectum, the syringe being used, when necessary, to help the passage of the opaque mixture with light pressure. It often reaches the cæcum in 2 minutes and almost invariably within 5 minutes. When the examination is complete, part can be run out through the tube, the rest being evacuated in the ordinary manner; a further inspection with the X-rays is then made. Additional information, especially as to the presence of polypi, can often be obtained by injecting air into the colon after the greater part of the opaque enema has been evacuated.

An organic stricture of the colon generally obstructs the passage of the fluid, the shadow ending at the seat of the obstruction, which can be overcome only incompletely or not at all by waiting an additional 10 minutes, by increasing and decreasing the pressure of injection, by massage and by changes in posture. The flow of the enema is often prevented in cases of growth long before there is any clinical evidence of obstruction; the bowels may still act normally or diarrhœa may be present, and an opaque meal may pass through the whole colon without delay. This is probably due to the occurrence of a spasmodic contraction of the bowel, which occurs at the seat of obstruction as soon as the enema reaches and distends the part immediately below it.

An opaque meal or, more frequently, an opaque enema may show the presence of a filling defect in the colon caused by a growth. The latter also shows the exact length and position of fibrous strictures, and it is generally the most satisfactory way in which the presence of diverticula can be determined.

EXAMINATION OF FÆCES

The consistence, smell, colour and reaction of the stools when no aperient is being taken should be noted, abnormal acidity indicating excessive fermentation and abnormal alkalinity excessive putrefaction. The presence of mucus with solid stools is not in itself a sign of disease, but if it is mixed with blood or pus or present with fæces which are unformed though no aperient has been taken, some organic disease is certainly present. The presence of mucus with hard scybala or with soft stools obtained after the use of an aperient is due to the normal reaction of the colon to a mechanical and chemical irritant respectively, mucus being secreted in order to protect the mucous membrane. Blood by itself may come from hæmorrhoids or a rectal polyp; if associated with mucus or pus or both, inflammation or cancer of the anal canal, rectum or colon must be present. The larger the fragments of mucus and the brighter the colour of the blood the lower is their source. The presence of pus always indicates disease of the pelvic colon or rectum.

Pale, bulky stools generally indicate the presence of excess of fat. It is important to ascertain whether this is chiefly in the form of neutral fat, as in pancreatic insufficiency, or in the form of fatty acids and soaps, as in

deficient absorption caused by jaundice, sprue, cœliac disease and obstruction of the lacteals with normal pancreatic digestion. This can generally be decided by microscopical examination, but in doubtful cases an accurate chemical analysis should be undertaken.

Microscopic examination may reveal the presence of blood corpuscles, pus, amœbæ or their cysts, and the ova of intestinal worms, in addition to fragments of animal and vegetable food which have escaped digestion.

A bacteriological examination of the stools should always be made in cases of diarrhœa, with or without colitis. The presence of a relative excess of enterococci or *B. coli communis*, the normal inhabitants of the colon, or of strains of streptococci or *B. coli* which are not normally present, or of parenteric, enteric, dysentery and tubercle bacilli may be discovered. If a sigmoidoscopic examination is made, a swab should be taken for bacteriological examination from the mucous membrane; if any mucus or pus is seen, this should also be taken for examination. In doubtful cases the agglutinating power of the patient's blood for abnormal bacteria isolated from the stools should be tested.

Occult Blood

When blood is swallowed or is derived from an ulcer or growth in the œsophagus or stomach or an ulcer in the duodenum it is evacuated in the stools partly as acid hæmatin and partly as hæmatoporphyrin. Both also appear in the stools when the blood originates in the colon unless diarrhœa is present, when the blood does not remain in the bowel long enough for the former to be converted into the latter. The chemical tests for "occult blood"—traces of blood insufficient to produce any change in the appearance of the fæces—depend upon the conversion of a substance with little or no colour, such as guaiac or benzidine, into a coloured substance when oxidised by hydrogen peroxide in the presence of a carrier, such as hæmatin. The guaiac reaction is preferable to the benzidine, as, unlike the latter, it does not give a colour-reaction when iron salts are given by mouth; it can, therefore, be used in patients with ulcer who are receiving iron on account of post-hæmorrhagic anæmia. Hæmatoporphyrin, which contains no iron, gives neither reaction. A spectroscopic examination of the stools should also be made, as even considerable quantities of hæmatoporphyrin, which is occasionally present in the absence of acid hæmatin, would otherwise escape recognition. Moreover, a positive spectroscopic finding is valuable confirmation of a positive chemical reaction, as, although it is much less sensitive, there is less chance of error.

Before the stools are examined the patient is given a hæmoglobin-free diet. Chlorophyll should also be excluded, as it gives a feebly positive guaiac reaction, and its many-banded spectrum may cause confusion in the spectroscopic examination. A charcoal biscuit is given with the first meal on the restricted diet, and the first and subsequent stools passed when the fæces are no longer blackened by the charcoal are examined. For the guaiac test a small amount of fæces is macerated with glacial acetic acid into a thin paste. An equal quantity of ether is then added to extract the pigment and the ethereal extract is poured off, some being kept for the spectroscopic examination. Two or 3 drops of tincture of guaiac are added to the re-

mainder; a small quantity of ozonic alcohol is then poured in, and a change of colour is looked for at the junction of the two fluids. A "positive" reaction is one in which a deep blue colour rapidly appears; a "feeble positive" reaction is one in which the colour is faint purple, bluish or greenish. If 1 c.c. of blood enters the stomach or intestines, the next day's stool will give a faintly positive reaction.

A positive guaiac reaction signifies the presence of occult blood. A negative guaiac reaction proves its absence, except occasionally at the end of a period of hæmorrhage, when the spectroscopic test may alone be positive, as the traces of blood still present may then be completely converted into hæmatoporphyrin, which gives a characteristic spectrum, but does not give the chemical reaction.

By the spectroscopic test of the stools one can recognise (1) the acid hæmatin, which also gives a positive guaiac and benzidine test, and (2) the other hæmoglobin derivatives, *i.e.* porphyrins, which do not give a positive colour-reaction. The spectrum of acid hæmatin is so faint that it can be seen only in fairly concentrated solutions: the typical band of acid hæmatin (λ 620) is found only when considerable quantities of blood are present in the stools.

Small amounts of chlorophyll are easily discovered by the characteristic band in red on λ 662, *i.e.* left of λ 650, whereas the band of alkaline porphyrin lies right of λ 650 on λ 630. Moreover, on addition of HCl the bands of alkaline porphyrin immediately change to the acid spectrum (a narrow band in red (λ 605-600) and a broad band in yellow (λ 590-550)), whereas the chlorophyll spectrum remains unaltered.

In the absence of hæmorrhoids and rectal polypi (which may be quite latent) and of bleeding from the mouth, throat and nose, the presence of occult blood in the stools is strong evidence that an ulcer or growth is present in the œsophagus, stomach or intestines. It is occasionally found in gastritis, with gall-stones, diverticulitis and localised adhesions involving the alimentary tract.

PROCTOSCOPIC AND SIGMOIDOSCOPIC EXAMINATION

Wherever there is any possibility of organic disease of the pelvic colon or rectum a proctoscope and, if necessary, a sigmoidoscope should be passed after a preliminary digital examination. No special preparation is required, but the patient should endeavour to get his bowels emptied as completely as possible without the aid of aperients or enemata shortly before the examination. The instrument should be passed without an anæsthetic in the knee-elbow position.

The passage of a proctoscope requires little experience, whereas a sigmoidoscope should be used only by experts. As the rectum is involved from the onset and is the last part to recover in ulcerative colitis, proctoscopy gives all the information required, and it has the advantage of allowing examination from a shorter distance. Moreover, the pelvi-rectal flexure, which is the commonest situation of cancer, is within its range. But when nothing abnormal is found with a proctoscope in suspected cases of malignant disease, it is essential to pass a sigmoidoscope.

FUNCTIONAL DISORDERS OF THE INTESTINES

CONSTIPATION

Definition.—Constipation may be defined as a condition in which no residue of the food taken during one day is excreted within the next 48 hours.

Ætiology and Pathology.—Constipation may be due to (1) the passage through the colon being delayed, whilst defæcation is normal—colonic constipation; (2) the evacuation from the pelvic colon and rectum being inadequately performed, whilst the passage through the colon is normal—dyschezia; and (3) insufficient formation of fæces.

1. Colonic Constipation.—Delay in the passage of fæces through the intestines is due to their motor activity being deficient, or to the force required to carry the fæces to the pelvic colon being excessive. The motor activity of the colon may be deficient owing to deficient reflex activity, inhibition, or uncontrolled and irregular action. There is no evidence that it is ever due to actual weakness of the muscular coat. The reflexes which maintain intestinal activity may be deficient owing to lack of mechanical and chemical stimulants in the food, or to some endocrine deficiency as in hypothyroidism. The inhibitory sympathetic nerves may be stimulated centrally by depressing emotions, and reflexly in painful diseases and injuries of any part of the body, but particularly of the abdominal and pelvic viscera.

Constipation may result from painful spasm, induced reflexly by the presence of an irritant in the colon of a patient with an abnormally excitable nervous system (*spastic constipation*). The irritant which gives rise to the exaggerated reflexes is in most cases hard fæces, which may have been retained as a result of constipation caused by insufficient and unsuitable food and of dyschezia. Spasm may result from irritation by organic acids in intestinal carbohydrate dyspepsia, in which constipation may alternate with diarrhœa. Spastic constipation is a constant symptom of diverticulitis. The reflex may also be excited by disease in other parts of the abdomen, especially the gall-bladder and appendix. Similar spasmodic contractions of the intestines occur as a result of excessive smoking and in lead poisoning.

The work to be done by the intestinal musculature is excessive when the fæces are abnormally hard and dry owing to insufficient consumption of water or its excessive loss in the urine or sweat, and when there is a diminution in the intestinal lumen owing to organic stricture.

2. Dyschezia.—Dyschezia may be due to inefficiency of the defæcation reflex, to abnormally hard and bulky fæces requiring excessive force for their evacuation, or an obstacle to efficient defæcation, such as spasm or congenital or acquired strictures of the anal canal. Dyschezia due to inefficient defæcation is the most common cause of severe constipation. It often originates in neglect to respond to the call to defæcate owing to laziness, insanitary condition of the w.c. or false modesty. The conditioned reflex upon which defæcation normally depends is gradually lost. The rectum dilates so that an increasing quantity of fæces is needed to produce the adequate internal pressure required to give the sensation of fullness which is the natural call to defæcation. Finally the sensation is lost com-

pletely. But the patient is still capable of emptying his rectum if he tries. He has, however, by now often convinced himself that he cannot get his bowels to open unless he takes enemata or such enormous doses of aperients that the fluid fæces practically act as enemata. He suggests to himself that his rectum is powerless to act by itself; the dyschezia is then in part hysterical.

Dyschezia may be due to various other causes, such as weakness of the voluntary muscles of defæcation, the assumption of an unsuitable position during defæcation, and voluntary inhibition from fear of pain in diseases of the anal canal. But whatever the primary cause, the final result is the same. The conditioned defæcation reflex is lost, and the incomplete evacuation of the rectum results in the accumulation of fæces and consequent dilatation of the rectum.

Careful training is required from earliest infancy in order to develop the defæcation reflex. Neglect of this, together perhaps in some cases with a congenital deficiency of the muscle-sense of the rectum, is the cause of the dyschezia of infants, in whom the slight additional distension produced by the introduction of a finger or a piece of soap into the rectum results in an adequate stimulus.

The rectal muscle-sense is abolished or defective in diseases of the spinal cord in which the defæcation centre itself or the fibres connecting it with the brain are involved.

3. The third great class of constipation is due to the quantity of fæces formed being insufficient to produce an adequate stimulus in the pelvic colon and rectum, and to a less extent in the rest of the colon. The insufficient bulk of fæces is due to an inadequate quantity of food residue reaching the colon as a result of anorexia or of œsophageal or pyloric obstruction, or to unusually complete digestion and absorption of food, the result of a "greedy bowel."

Symptoms.—Many people regard themselves as ill if they do not have one action of the bowels a day; but this is really nothing more than a question of convenience, being found to suit the habits and diet of the majority of civilised people. Perfect health may be maintained by individuals who defæcate regularly two or three times a day, and by others who obtain an evacuation once in two, three or more days. The latter, so long as defæcation, when it does occur, is complete, can no more be regarded as diseased than those otherwise normal people, whose hearts beat only forty or fifty times a minute. The majority, however, although they may suffer no inconvenience for a considerable time, finally develop symptoms due to fæcal accumulation, gradually increasing quantities of fæces being retained. For practical purposes, therefore, an individual may be considered constipated if his bowels are not opened at least once in every 48 hours. A less frequently recognised variety of constipation is that in which insufficient fæces are excreted, although the bowels may be opened every day—a condition analogous to retention of urine with overflow.

It is important to distinguish the symptoms of constipation from those of the conditions which may give rise to it. There is no doubt that anxiety neuroses and hypochondriasis, epilepsy, asthma, nephritis, diabetes, painful pelvic disorders and many other diseases may be greatly aggravated by constipation. Apart from these conditions, headache, fatigue, anorexia and pigmentation of the skin may result directly from intestinal intoxication

and, with the exception of pigmentation, from the reflex effects of constipation. Toxic symptoms never develop unless stasis occurs in the cæcum and ascending colon, in which the fæces are still soft, and then only if it is associated with impairment of the functional efficiency of the liver, which normally destroys intestinal toxins or renders them innocuous, or of the kidneys, which normally excrete any toxins which have escaped the liver. Reflex symptoms, on the other hand, occur chiefly in dyschezia as a result of the pressure produced by hard fæces. The latter differ from the former by their almost instantaneous disappearance on defæcation.

Fæcal retention is a common cause of intestinal flatulence and colic. In rare cases a fæcal tumour may form, generally in the pelvic colon, and give rise to obstruction. A fæcal accumulation in the rectum may cause hæmorrhoids, pruritus ani, catarrhal proctitis and neuralgic pains in the perineum, back and down the legs. Hard fæces make defæcation painful, and their passage may give rise to anal ulcers.

Diagnosis.—It is comparatively rare for a patient to consult a doctor on account of constipation without having already attempted to cure himself

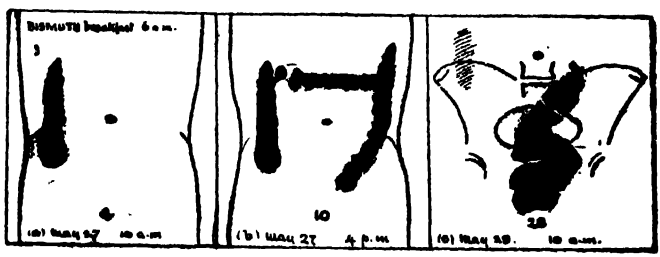

FIG. 17.—Dyschezia in a girl of 17, whose bowels had not been opened for 5 weeks when admitted to Guy's Hospital. (First case of constipation examined with X-rays: May 1907.)

with aperients. But no accurate diagnosis can be made until it has been ascertained whether he is actually constipated at all. The symptoms generally ascribed to auto-intoxication caused by intestinal stasis are often really produced by purgatives, which lead to the excessive production of toxins by hastening the half-digested contents of the small intestine into the cæcum, where fermentation and putrefaction are consequently increased. Purgatives also cause the contents of the transverse, descending and pelvic colon to be fluid instead of solid, so that absorption of toxins continues throughout the whole length of the bowel instead of in the cæcum and ascending colon alone. In spite of his probable protests the patient is instructed to see what happens if no drugs are taken for three days, an effort being made to open the bowels each morning. In most cases he loses his abdominal pain and his so-called toxic symptoms. The bowels are often opened daily, in which case a diagnosis of hysterical pseudo-constipation can be made—hysterical because the patient had suggested to himself, as a result of faulty education combined with the reading of pernicious advertisements, that he was constipated and required aperients to keep himself well, whereas a little psychotherapy, in the form of explanation of the physiology of his bowels and the origin of his symptoms and persuasion to try to open his bowels each morning

without artificial help, results in a cure. In some cases, however, the patient does not succeed in opening his bowels, although he may feel more comfortable than when he was taking drugs. A second abdominal and rectal examination should then be made. If no sign of organic disease is present and the rectum is found to be filled with fæces, dyschezia can be diagnosed. In spite of this the patient has no desire to open his bowels; a normal individual would feel an urgent call to defæcation under such conditions, but the rectum has dilated as a result of being constantly full of fæces and the call to defæcation is no longer felt.

In severe cases it is advisable to investigate the motor activity of the intestines with the X-rays, a barium meal being given after the patient has discontinued taking aperients. Ileal stasis should be diagnosed only if no trace of barium has reached the cæcum 6 hours after the opaque meal, or if a considerable quantity of barium-containing chyme is still in the end of the ileum 6 hours after evacuation of the stomach is complete. If most of the barium is still in the cæcum and ascending colon at the end of 24 hours, stasis is present, even if a little has passed to the more distal parts of the colon; but a faint shadow of the cæcum is often visible in normal individuals even 3 days after the meal. If the splenic flexure is reached in 24 hours, and the greater part of the barium is in the transverse colon at the end of 48 hours, there must be stasis in this part of the bowel. In dyschezia most or all of the barium has accumulated in the rectum in 24 hours (Fig. 17). In pelvic colon dyschezia a similar accumulation occurs in the pelvic colon, but the rectum remains empty.

Treatment.—Under no circumstances should the patient fail to make an effort to open his bowels after breakfast, even if he feels no desire to do so, and a call to defæcation felt at any other hour in the day should be obeyed at once. Sufficient time should be spent over the act of defæcation, and it is often advisable to pay two visits to the closet at short intervals, perhaps before and after breakfast. In order to prevent the temptation to hurry over defæcation, the closet should be clean, devoid of smell and properly warmed in winter. In dyschezia with weak abdominal muscles a footstool, 9 inches lower than the seat, should be provided. In many cases of dyschezia no treatment is required beyond explaining to the patient the nature and cause of his condition, and persuading him to give up aperients and to make an effort to empty his rectum, which he must realise is quite capable of doing its work. By perseverance it is generally possible to re-develop the lost conditioned reflex upon which normal defæcation depends.

It is most important to see that sufficient food is taken, as constipation is often as much due to its insufficient quantity as to its unsuitable quality. The diet should contain an increased proportion of vegetable foods, especially those which contain much cellulose and organic acids. Fresh or dried fruit should be taken three times a day, and green vegetables or salad should be eaten at lunch and dinner. Stewed prunes taken at breakfast, the number being regulated according to the degree of constipation, are especially valuable. Porridge and cream and wholemeal brown bread are also useful. Sufficient fluid should be drunk; a glass of cold water taken on rising in the morning often helps the bowels to act after breakfast.

The majority of cases of constipation can be cured without drugs if proper treatment is instituted at a sufficiently early stage. In dyschezia purgatives

act only when fluid stools are produced, colic and toxic symptoms often resulting and a considerable quantity of fluid and nutritive material being wasted. In the treatment of diseases which are aggravated by co-existing constipation, purgatives should be regularly given. They are also useful for making the stools soft when straining at stool is accompanied by danger, as in patients with weak hearts or high blood pressure. In colonic constipation, when non-medical treatment proves insufficient, purgatives must also be used, but an effort should be made to dispense with them at the earliest possible moment. The stool produced by an aperient should be normal in size and consistence; the dose should be so regulated that one stool is passed every day and the desire to defæcate is felt immediately after breakfast. It should cause no pain or discomfort, and should not irritate the intestinal mucous membrane sufficiently to lead to the appearance of mucus in the stools. An infusion of senna pods in cold water is particularly useful, as senna acts on the colon alone, and the dose can be regulated from day to day by the patient; an attempt should be made at intervals to reduce the number of pods by one at a time, until finally none may be required.

In constipation caused by a greedy bowel the bulk of the fæces must be increased by the administration of liquid paraffin or of an unirritating vegetable mucilage, such as isogel or coreine, which pass through the intestines without undergoing decomposition or absorption. These preparations are valuable when the fæces are hard and dry; they are therefore useful in other varieties of constipation besides that due to a greedy colon, as fæces always become hard and dry as a result of their abnormal retention in the bowel. In dyschezia the soft stools which result from their use are expelled with less difficulty than ordinary fæces. From 60 minims to 1 fluid ounce of paraffin or double the dose of a plain 50 per cent. paraffin emulsion should be taken immediately after one, two or three meals every day. Sixty grains of isogel or coreine, which absorbs water to form a bulky gelatinous mass which becomes intimately mixed with the fæces, is taken with one or more meals in addition to or as a substitute for paraffin.

The majority of cases of moderately severe constipation are more or less cumulative, excess of fæces being always present in the large intestines. It is therefore necessary that the colon should be completely evacuated before other methods of treatment are adopted. This can best be done by washing the colon out with a pint and a half or two pints of warm water run into it from a douche-can or funnel at low pressure through a soft catheter inserted just beyond the anal canal. The regular use of enemata, Plombières douches and of continuous intestinal lavage with many pints of fluid are very harmful both from a physical and psychological point of view.

It is essential in treating dyschezia to keep the rectum and pelvic colon empty, so that they may in time regain their normal tone and contractile power. This can be accomplished by the use of a 1-ounce enema consisting of equal parts of glycerin and water every morning, if a prolonged attempt to defæcate naturally has proved unsuccessful The strength of the enemata should be gradually reduced by replacing a drachm of the glycerin by water every other day until only water is used. As a rule the normal defæcation reflex and with it the tone and contractile power of the rectum slowly return.

When dyschezia is due to inability of the pelvic colon to empty its contents

into the rectum, six ounces of paraffin should be injected on going to bed and retained during the night; the bowels are then generally opened without difficulty in the morning. If, however, they fail to act, a plain water enema should be given.

When the sphincter ani is in a condition of spasm as a result of inflamed hæmorrhoids or an anal ulcer, or when the anal canal is congenitally too narrow or a stricture has followed an operation for hæmorrhoids, complete relief can be obtained by dilating the passage by means of diathermy applied locally through a conical electrode.

Regular exercise in the open air is a valuable means of preventing constipation, especially in individuals who follow a sedentary occupation. When any of the voluntary muscles of defæcation are weak, considerable benefit can be gained by the performance of remedial exercises every morning and evening. Special attention should be devoted to the levator ani muscles, especially in women in whom the pelvic floor has been injured during parturition, and in cases in which there is any tendency to prolapse on straining at stool (see p. 750). Stasis in the proximal part of the colon may be benefited by massage applied directly to the affected part. Its efficacy is greatly increased if the first treatment is given during an X-ray examination, as the masseur can then see the exact position of the colon and can find what manipulations have most effect upon it.

DIARRHŒA

Definition.—Diarrhœa is a condition in which unformed stools are passed. Defæcation generally occurs several times in the day, but mere frequency of defæcation is not diarrhœa, for this may even be associated with constipation. The bulk of fæces excreted in 24 hours is generally excessive, but this again may occur without diarrhœa, as excessive fæces are occasionally formed when the passage through the alimentary canal is not abnormally rapid. The one essential factor in diarrhœa is the abnormally rapid passage of the food residue through the alimentary canal.

Ætiology.—1. Excessive Stimulation of Motor Activity.—The most common cause of diarrhœa is the presence in the food of excess of the mechanical and chemical stimulants of intestinal activity. Thus over-indulgence in green vegetables, salads and especially unripe fruit is a familiar cause. Chemical irritants may also be swallowed in decomposing food, as in some cases of fish and meat poisoning, but food may also cause diarrhœa by giving rise to a bacterial infection of the intestine. Diarrhœa very frequently results from the habit of taking aperients, either in excess of what is required for the correction of chronic constipation, or even when the bowels left to themselves would act quite normally. Thus many of the symptoms often ascribed to constipation are really due to the diarrhœa caused by purgatives, as it results in the absorption of excess of poisons from the too fluid fæces.

Chronic diarrhœa is a common sequel of the acute diarrhœa following infection with a pathogenic organism which gains access to the intestines in contaminated food or water, and it may follow acute general infections such as influenza. In both cases the subsequent diarrhœa may be gastrogen-

ous (*vide infra*) and associated with achlorhydria resulting from gastritis caused by the infection, and not the direct result of bowel infection. In some cases the infection is derived from a septic focus in the mouth, nose or pharynx, and in rare cases recurrent subacute appendicitis is the source of a chronic infection of the colon. Some infective bacteria, such as those of the parenteric group, act chiefly on carbohydrates and may lead to excessive fermentation. Others, such as streptococci and various anaerobes, act on proteins and lead to putrefactive diarrhœa. Severe intestinal carbohydrate dyspepsia (p. 644) may give rise to chronic diarrhœa or alternating constipation and diarrhœa, and deficient digestion of proteins, resulting from either gastric or pancreatic insufficiency, may lead to a non-infective putrefactive diarrhœa. Deficient digestion of fat and deficient absorption of fatty acids and soaps give rise to fatty or soap diarrhœa respectively (*vide*, p. 626).

Diarrhœa is often gastric in origin. This *gastrogenous diarrhœa* may occur when the gastric juice is deficient or absent. An abnormal number of organisms reaches the intestines in these circumstances, as the partial protection afforded by the bactericidal action of the hydrochloric acid in the stomach is lost. As in addition to the digestion of meat in the stomach the connective tissue of meat and the cellulose of vegetables are normally softened by the hydrochloric acid of the gastric juice, undigested lumps of meat and fragments of vegetable leave the stomach and pass through the small intestine to the colon, where they are liable to undergo bacterial decomposition. The irritation of the mucous membrane of the intestines by the insufficiently divided fragments of food and by the products of bacterial decomposition leads to diarrhœa, which may become aggravated by secondary enteritis or entero-colitis if the irritation is sufficiently intense or prolonged. Similar gastrogenous diarrhœa may occur after the performance of a gastro-jejunostomy or partial gastrectomy, the food leaving the stomach with such rapidity that the intestines are overwhelmed with undigested and irritating food.

Lastly, chemical stimulants to intestinal activity may be produced in the body and excreted into the colon; this is the cause of diarrhœa in uræmia, hyperthyroidism and septicæmia.

2. Over-excitability of the Neuro-muscular Mechanism which controls the Intestinal Movements.—(*a*) *Post-prandial diarrhœa.*—Under normal conditions the entry of food into the empty stomach gives rise to a gastro-colic reflex, which is the chief stimulus to the movements of the colon. In most individuals this is followed by defæcation only after breakfast, as the pelvic colon is then full, and the sudden passage of fæces from it into the rectum gives rise to the call to defæcation. Sometimes the gastro-colic reflex is abnormally active. This may manifest itself after breakfast; a formed stool is passed first, but in the course of the next half-hour or hour one or more loose stools are passed in addition. In severer cases the bowels are also opened after dinner and less frequently after lunch, the stools again being often soft or fluid.

(*b*) *Nervous diarrhœa.*—It is not uncommon for a fright to result in the immediate passage of a semi-fluid stool. In some patients, who are often not otherwise neurotic, attacks of diarrhœa occur whenever they are in any place where it would be awkward for them to relieve themselves. When this has once happened, it is likely to recur under similar circumstances,

largely owing to fear that it will do so. Post-prandial and nervous diarrhœa are often associated together, a patient suffering from the former being particularly likely to feel an urgent desire to defæcate if he is at a dinner-party or in a railway carriage without a lavatory.

Diarrhœa, whatever its cause may be, tends to be worse after meals, especially breakfast, and it is occasionally also influenced by nervousness; it is important, therefore, to exclude some other primary cause before diagnosing a case as one of pure post-prandial or pure nervous diarrhœa.

(*c*) *Irritable bowel.*—When the mucous membrane of any part of the intestines is inflamed or ulcerated, mechanical and chemical stimulants are likely to produce an excessive reflex response, so that the diarrhœa which is probably already present is aggravated. Apart from this many people, who have lived in the tropics and have suffered there from dysentery or from diarrhœa due to some less defined cause, continue to be liable to diarrhœa for many years after their return to a temperate climate.

3. Organic Intestinal Disease.—(*a*) *Enteritis.*—The profuse, watery diarrhœa of acute food poisoning and acute infections such as abdominal influenza and septicæmia is a result of acute enteritis, which is generally accompanied by acute gastritis, especially if vomiting is present, but the colon is often spared. The irritating products of the excessive bacterial activity resulting from the stasis in organic obstruction of the small intestine give rise to enteritis; consequently diarrhœa and not constipation is almost always present in chronic small intestine obstruction. In all these conditions the chyme from the stomach passes so rapidly through the small intestine that they are quite fluid and very bulky when they reach the cæcum; they consequently act as an enema and are almost immediately evacuated, even if the colon remains quite healthy.

(*b*) *Colitis.*—Diarrhœa is a constant symptom of acute inflammation of the colon, except in the rare cases in which it is confined to the proximal part. Thus it is always present in ulcerative colitis and bacillary dysentery, in which the disease begins and remains longest in the pelvic colon and rectum, but it may be absent in mild cases of amœbic dysentery in which the cæcum alone is involved. Diarrhœa may occur in carcinoma of the colon, especially the distal part, before the lumen has been narrowed sufficiently to lead to fæcal retention. The diarrhœa in these conditions is due to irritation of the bowel by the products of bacterial decomposition of the albuminous exudate of the diseased parts, and in colitis also to deficient absorption of fluid by the inflamed mucous membrane.

Symptoms.—The chief and sometimes the only symptom of diarrhœa is the abnormally frequent passage of abnormal stools. In small intestine diarrhœa discomfort and colicky pain are often felt round the umbilicus. In severe cases of diarrhœa, whatever its origin, discomfort or even pain is felt over the whole of the lower part of the abdomen for a short time before the bowels are opened. It may be followed by a sensation of soreness, but the abdomen is neither tender nor rigid, and warm applications generally relieve it. Occasionally severe colic occurs, which may be temporarily relieved each time the bowels are opened or flatus is passed. The passage of a large and watery stool is often followed by a feeling of exhaustion and faintness, which may be accompanied by sweating and coldness of the extremities and occasionally even by syncope.

In severe cases of acute diarrhœa and in persistent cases of chronic diarrhœa the nutrition suffers and the patient loses weight; sometimes an extreme degree of emaciation results. When the diarrhœa is associated with abnormal bacterial activity in the intestines, especially if this is of the putrefactive type, symptoms of intestinal toxæmia may develop.

Diagnosis.—When a patient complains of diarrhœa, it is first necessary to ascertain whether the passage of fæces through the intestines is really taking place with abnormal rapidity. Many people think that frequent defæcation, particularly if the stools are in part fluid, is sufficient evidence that diarrhœa is present, whereas this is by no means necessarily the case. The stools of every patient supposed to be suffering from diarrhœa should be examined; if they are of a uniform semi-solid or fluid consistence, true diarrhœa is probably present, whereas numerous stools, if they are small and solid, and fluid stools containing small solid fragments suggest a diagnosis of pseudo-diarrhœa. In a doubtful case, 2 or 3 charcoal lozenges should be given with some food immediately after the bowels have been opened in the morning; each stool is now examined and the time which elapses before black fæces are passed is noted. If charcoal is seen in the stools within 12 hours, true diarrhœa is present; if in less than 4 hours, the small intestine must be involved as well as the colon. If no charcoal appears within 48 hours, constipation and not diarrhœa is present. A series of X-ray examinations after a barium meal affords a more accurate method of determining the rate of passage through the alimentary canal, and it has the advantage of showing in what part of the bowel the rate is excessive. In small intestine diarrhœa the head of the opaque meal may reach the cæcum within an hour or two; when the colon alone is involved, it arrives after the usual interval of 3 or 4 hours.

The most common cause of pseudo-diarrhœa is dyschezia; although the rectum is never properly emptied, the patient feels a constant desire to open his bowels, and as a result of his efforts a very small quantity of hard fæces may be passed. The constant presence of fæces in the rectum calls forth the secretion of clear mucus. In slight cases there may be nothing more than a thin layer of mucus over the hard lumps of fæces; in severer cases a larger quantity of fluid mucus, which is often stained brown, is passed either alone or with hard particles of fæces. In all such cases the discovery of solid fæces in the rectum immediately after the bowels have been opened should remove any further doubt as to the diagnosis. A growth of the rectum or pelvic colon, and less frequently a growth in other parts of the colon, though rarely on the proximal side of the splenic flexure, may lead to pseudo-diarrhœa, fæces being retained above the growth, whilst the serous and often blood-stained exudation from its surface, mixed with mucus produced by the irritant action of the exudation on the mucous membrane below it, are passed at more or less frequent intervals, so that the patient regards himself as suffering from diarrhœa. The character of the stools should at once make it obvious that endoscopic and radiological examinations are required, even if nothing abnormal is felt on abdominal or rectal examination.

When it is known that genuine diarrhœa is present, it is next necessary to determine whether it is due to a functional or an organic cause. The history is often a great help. Post-prandial or nervous diarrhœa of long

duration is generally gastrogenous. An acute onset suggests that the cause is some toxic or infective agent, whereas a more gradual onset of chronic diarrhœa in a middle-aged individual, who has hitherto been regular or constipated, suggests the possibility of a growth. A careful abdominal and rectal examination should be made in every case; the former may reveal the presence of a tumour or an abnormally dilated or contracted condition of the colon; by means of the latter the existence of ulcerative colitis may sometimes be recognised, as well as the presence of a growth in the rectum or pelvic colon. In doubtful cases an endoscopic examination should also be made before deciding that the diarrhœa is functional in origin, as the mucous membrane of the accessible part of the colon is almost always involved when diarrhœa is due to some form of colitis.

The examination of the stools is of the greatest importance, as it gives valuable indications for treatment as well as helping in diagnosis. In small intestine diarrhœa the stools are watery, whereas in colonic diarrhœa they are unformed but not fluid. The presence of mucus indicates active inflammation, and blood with or without pus simple or malignant ulceration. Thus the watery diarrhœa caused by enteritis can be distinguished from that caused by excessive irritability or irritation of the small intestine by the presence of flakes of mucus floating in the fluid fæces. In acute enteritis the mucus is often blood-stained and microscopical examination shows the presence of red corpuscles, degenerated epithelial cells and pus cells; as the inflammation subsides the mucus becomes cell-free and finally disappears. Similarly the unformed, but not watery fæces of an irritable or irritated colon can be distinguished from the fæces of colitis by the presence of mucus, pus and blood in the latter.

The presence of excess of starch, meat fibres or fat indicates a small intestine diarrhœa. Excess of undigested starch is found on microscopical examination in fermentative diarrhœa, and of striated muscle fibres in putrefactive diarrhœa. The fæces are often frothy and have an acid smell and reaction when fermentation is excessive; they are alkaline and have a putrefactive odour when excessive putrefaction is present.

The stools passed when fat is insufficiently digested or absorbed are easily recognised by their pale colour and increased bulk. If the excess is in the form of neutral fat, the stools are oily (*fatty diarrhœa*), and pancreatic insufficiency can be diagnosed; striated meat fibres are also likely to be present. This condition is, however, rare in the absence of jaundice caused by obstruction of the common bile duct. More frequently most of the fat is present as fatty acid and soaps (*soap diarrhœa*), showing that pancreatic digestion is normal, but that absorption is deficient. This may result from absence of bile salts in obstructive jaundice, from the functional disorder of the small intestines which is the cause of *cœliac disease* in children, and *sprue* and *non-tropical sprue* in adults. Soap diarrhœa is also caused by obstruction of the lacteals by tuberculous, simple inflammatory or secondary malignant disease of the mesenteric glands. In the case of the latter the stools becomes perfectly normal on a fat-free diet, the digestion of meat and vegetable food being unaffected. In soap diarrhœa almost all the calcium in the food combines with fatty acid to form calcium soap in these conditions; the blood calcium is consequently diminished, and tetany may result. In children growth is greatly impaired, and deformities result from the softness

of the long bones. The inability of the intestines to absorb fat may be associated with deficient absorption of sugar, iron (causing microcytic anæmia), hæmopoietin (causing pernicious anæmia), neuropoietin (causing subacute combined degeneration of the cord), and vitamins A, B, D, E and K.

A bacteriological examination should always be made in the hope that the nature of any infection which is present may be discovered.

Prognosis.—If thorough treatment is instituted from the onset, the prognosis of diarrhœa is good, unless it is due to some serious organic disease. If, however, it is neglected, strict treatment must be continued for a prolonged period in order to be successful. This is particularly the case when the diarrhœa is infective in origin.

The tendency to post-prandial and nervous diarrhœa often remains throughout life, though considerable improvement and even a cure can result from treatment. Unlike other forms of diarrhœa, they rarely affect the general health, and are chiefly troublesome on account of the inconvenience they cause.

Treatment.—*Acute diarrhœa.*—The patient should be kept warm and at rest in bed until the attack has completely subsided. If it is due to food poisoning and he is seen within 12 hours of the onset, he should be given from ½ to 1 ounce of castor oil to clear the irritant material out of the small as well as the large intestine, unless the diarrhœa is so severe that it appears probable that this has already occurred. No food should be given for 24 hours or even longer in severe cases, but the patient may drink as much water as he likes. Sweetened arrowroot made with water should then be given, but nothing else until the diarrhœa has ceased. Milk, junket, bread and butter, and milk puddings are next allowed, after which a gradual return should be made to an ordinary diet, the speed with which this is done depending on the severity of the case. The only drugs which are of real use in acute diarrhœa are kaolin and opium and its alkaloids. A tablespoonful of kaolin should be given three times a day. If the diarrhœa shows no signs of abating after 24 hours, codeine should be given, the dose being regulated according to the severity of the diarrhœa and the general condition of the patient, but sufficient must be given to stop the diarrhœa in 48 hours. If the diarrhœa is accompanied by vomiting, a test-meal should be given about a month later, even in the absence of all symptoms, as the accompanying acute gastritis may have led to achlorhydria, which is likely to give rise to chronic diarrhœa or other trouble later unless the underlying chronic gastritis is overcome.

Chronic diarrhœa.—In all cases of chronic diarrhœa recovery occurs most rapidly if the patient remains in bed during the first few days of treatment. In many instances the diarrhœa, which may have been present for months, disappears in a few days, and the patient may even become constipated. Unless, however, other treatment is instituted, the diarrhœa is very likely to return as soon as he gets up again. As the improvement which results from staying in bed is due in part to the rest and in part to warmth, it is important for the patient to avoid over-exertion and to keep his abdomen warm by means of a woollen binder for a considerable period after the symptoms have disappeared. Exposure to cold should be avoided as much as possible, and if the patient feels chilled at any time he should have a hot bath and go to bed at once; by these means he is likely to prevent a recurrence. Patients who have recently suffered from chronic diarrhœa should never go

to the tropics, and they should even avoid visiting the southern parts of Europe, as a slight intestinal attack from bad food is likely to have much more serious results with them than in an individual who has not before suffered from any intestinal disorder.

The successful treatment of chronic diarrhœa depends upon the recognition of its cause. The treatment of diarrhœa which is secondary to organic disease of the intestines, such as colitis and cancer, is considered elsewhere.

1. Excessive Stimulation of the Intestinal Movements.—Whatever the actual cause of the diarrhœa, it is important to avoid anything which could produce mechanical irritation of the colon. The food should be thoroughly chewed, and anything, such as new bread, cheese and tough meat, which is difficult to break up completely, should not be eaten. The patient must avoid all raw vegetables in salads and pickles, and cooked green vegetables are allowed only as purées. The pips and skins of fruit, whether raw, cooked or in jam, and currants, raisins and lemon peel in puddings and cakes must be avoided.

For the treatment of *fermentative diarrhœa*, *vide* Intestinal Carbohydrate Dyspepsia (p. 645). A lacto-vegetarian diet is most suitable for *putrefactive diarrhœa*; no meat should be allowed until the diarrhœa has ceased for 4 weeks, and high game and over-ripe cheese should be permanently avoided.

Fatty and *soap diarrhœa* stops at once on a fat-free diet. In severe cases, in which obstruction of the lacteals is present, it may be necessary for the patient to continue with this diet for the rest of his life.

Gastrogenous diarrhœa rapidly improves on the diet already described as suitable for putrefactive diarrhœa, but a relapse is certain to follow a return to an ordinary diet unless the achlorhydric gastritis is properly treated (*vide* p. 586). When the diarrhœa is infective in origin, a teaspoonful of a fresh liquid culture of *B. acidophilus* should be given fasting each morning.

2. Nervous and Post-prandial Diarrhœa.—Nervous diarrhœa is often completely uninfluenced by diet, but drugs, which diminish the activity of the gastro-colic reflex either peripherally or centrally, are very effective. A mixture containing 5 grains of potassium bromide and 5 minims of tincture of belladonna taken immediately before meals is all that is required in mild cases; in severer cases a small dose of codeine should be added. The exact dose of each drug must be varied to suit each patient, as different individuals react very differently to these drugs, especially to belladonna. When the diarrhœa has been completely controlled, the quantity of each drug should be gradually reduced; then the doses before lunch and dinner, and finally that before breakfast, can be discontinued. In some cases it is advisable to allow the patient to have a pill containing belladonna and codeine always with him, so that he can take one before going to a dinner-party or on any other occasion when he fears that he will have diarrhœa. He soon learns to trust so thoroughly in his pill that it probably acts more by suggestion than in any other way, and the dose can accordingly be progressively reduced until it is infinitesimal.

As in many cases of diarrhœa due to other causes the bowels act most frequently after meals, the treatment just described is often of use in conjunction with that required for the primary condition.

Arthur F. Hurst.

EPIDEMIC DIARRHŒA IN CHILDREN

Synonyms.—Summer Diarrhœa; Infective or Infectious Diarrhœa; Acute Gastro-Intestinal Infection; Acute Ileo-Colitis; Cholera Infantum.

The form of diarrhœa here spoken of used to be one of the chief scourges of infant life, but is certainly much less common now than formerly. It prevails epidemically in institutions, although sporadic cases may be met with at any time, and in hot seasons may become widespread, especially in large towns. It chiefly affects children below the age of 5, but is most fatal in the first year. Boys are more susceptible than girls.

Ætiology.—It is generally agreed that the disease is caused by infection with micro-organisms; but in spite of much research the bacteriology is by no means clear. It would appear that all cases are not due to the same organisms, and various members of the coli-typhoid-dysentery group have been blamed at different times. Recently particular attention has been paid to the Sonne strain of dysentery bacillus.

Next in importance as an ætiological factor must be put the influence of unhygienic surroundings, such as dirt, overcrowding, a contaminated milk supply, and want of cleanliness in feeding utensils. The infection is probably often conveyed by dust, and flies may act as carriers.

Any digestive derangement in the child may predispose to infection, and bottle-fed infants are specially liable. The disease appears to be to some degree contagious, and if introduced into a ward is apt to spread to unaffected infants. The influence of age and sex have already been referred to.

Pathology.—The changes found after death may be surprisingly slight, considering the severity of the disease, and vary materially in different cases and epidemics. As a rule the mucous membrane of the stomach and intestines is in a condition of "mucous catarrh." There may also be areas of congestion, with here and there small petechial hæmorrhages. The lymphoid tissue of the alimentary canal is often swollen, and in severe and protracted cases the solitary follicles in the colon and lower ileum may exhibit superficial ulceration.

Other organs, such as the liver and kidneys, show fatty or parenchymatous degeneration, whilst the lungs are often congested and œdematous, with, in protracted cases, patches of broncho-pneumonia in the lower lobes.

Symptoms.—The clinical picture is often very complicated, and if it is to be understood it is essential to realise that the disease is a general infection and not merely a disorder of the alimentary canal. The supervention of dehydration, acidosis or nephritis, with their own clinical manifestations, tend still further to perplex the observer and make it impossible for him to decide to what extent the symptoms are due to the primary infection or to these secondary developments.

The disease may start insidiously, with a gradually increasing diarrhœa; or the onset may be abrupt, with a rapid rise of temperature and early prostration. The diarrhœa is not necessarily a pronounced feature, and the worst cases are often those with fewest stools. The character of the motions varies; but in the early stage they are usually green, slimy and ill-digested, becoming dark and watery later. In the choleraic cases they are of the profuse "rice-water" type. When the colon is affected, visible mucus and blood may be

passed with much straining. The discharges are usually attended by colicky pain and the passage of flatus. Vomiting is generally present at the onset, but varies greatly in amount. The temperature is always elevated at some period of the disease, but the height, duration and course of the pyrexia are very inconstant. Hyperpyrexia may supervene towards the close in fatal cases. Prostration and circulatory failure are early features, and are shown by depression of the fontanelle, pallor, pinched features, an inelastic skin due to dehydration and coldness of the extremities. Where "intoxication" is a factor, consciousness becomes impaired, and the infant passes into a state of stupor, with intervals of restlessness, which may result in complete coma, sometimes terminating in convulsions. If acidosis is present, the respiration may show the characters of "air-hunger."

The urine is scanty, highly acid and contains a little albumin and a few hyaline casts. Acetone bodies may be present.

Course.—The course of the disease varies greatly. In the severest cases, especially those of the choleraic type, death may ensue within a few hours of the first onset of symptoms. In the milder forms the acute symptoms last for 2 or 3 days, and then gradually the prostration passes off and the stools assume a normal character. Only too often, however, the improvement is but partial, and the child lapses into a marasmic condition, with continued looseness of the bowels, from which recovery may only take place gradually. In all cases relapses, brought on either by re-infection, by meteorological conditions, or by injudicious feeding, are extremely common and apt to prove fatal.

In children above the age of 2 the disease usually assumes a milder form —prostration is not so severe and the range of temperature lower. Vomiting, also, is a less prominent symptom than in infants. Complete recovery is more frequent, and relapses and the continuance of the disease in a chronic form are rare.

In the special type of the disease commonly spoken of as "cholera infantum" the invasion is always abrupt, with a rise of temperature, followed by profuse vomiting and purging. Death usually ensues in a few hours, and is commonly attended by hyperpyrexia.

Diagnosis.—The diagnosis has to be made from simple non-infective diarrhœa, and for the increasingly common forms of diarrhœa secondary to respiratory tract and middle-ear infections. At first the differentiation may be impossible, but continued high temperature, early prostration and failure of rapid improvement on stopping food point to an infective origin. Careful physical examination will exclude secondary types. Epidemic prevalence is in favour of the primary variety. The nervous symptoms may simulate those of meningitis, but in case of doubt a lumbar puncture will determine the diagnosis. Very acute cases in which the colon is much involved, may resemble intussusception, but in the latter the onset is more dramatically sudden, the vomiting, collapse and passage of blood greater, and fever less, whilst in epidemic diarrhœa abdominal rigidity and tumour are absent.

Prognosis.—It is impossible to give any estimate of the fatality of diarrhœa, as it depends greatly on the type of the disease, and on the age, general condition and surroundings of the child, besides varying greatly in different epidemics. The younger the infant, and the poorer its general

nutrition, the worse is the outlook. The existence of rickets also greatly aggravates the danger. The frequency of the stools is of less importance in estimating the chance of recovery in any given case than the amount of prostration and the degree of inelasticity in the skin. Cases with prolonged high temperature and those of the choleraic type usually do badly. Persistence of vomiting also is a bad sign.

Treatment.—Unfortunately there is no specific treatment, and the principles to be aimed at are: (1) to stop the infection; (2) to eliminate and neutralise toxins; (3) to combat collapse; (4) to arrest the vomiting and purging.

1. In attempting to stop further infection, general hygienic measures are of great importance. Whenever it is possible, the child should be removed from a town, and isolated in a large, airy and well-ventilated room. Napkins should be removed and disinfected as soon as they are soiled, and the greatest cleanliness should be observed in regard to the feeding utensils and the nurse's hands. The collection of these cases in institutions should be avoided as far as possible.

If the case comes under observation early, an initial purge of castor oil or, if there is much vomiting, of calomel should be given to clear away decomposed matter from the bowel. Milk, which is the vehicle of infection, should at once be stopped, and for the first day or two the diet should be limited to half-strength normal saline, barley-water, weak tea, rice-water, 5 per cent. glucose, or weak broths, all of which may be given freely.

2. In order to favour the elimination of toxins, the action of the skin and kidneys should be promoted as much as possible. To this end, if the skin is very inelastic, tepid packs are useful, and these may be continued, if necessary, for several hours on end. If the urine is scanty, fluids should be given freely.

In the early stages of the disease no attempt should be made to arrest the diarrhœa entirely, as the retention of poisons would then be favoured. In addition to the initial purge, irrigation of the colon is a valuable aid in removing toxic material. Normal saline administered at a temperature of 100° F. through a rectal tube or large-sized red rubber catheter is the best solution to employ.

3. Collapse has to be obviated by saline infusion and the use of stimulants. Four ounces of normal saline may be injected under the skin of the flank every 6 hours, or saline and dextrose may be given intraperitoneally or into a vein. A continuous drip of normal saline is often life-saving.

Of stimulants, one of the best is alcohol. Ten to 15 drops of brandy may be given in a little water every 3 or 4 hours, or oftener; it should not be added to the feeds. Camphor is useful, and niketham ide (coramine) and adrenaline are also of value. If the collapse is extreme, recourse may be had to the mustard bath.

4. The arrest of the vomiting and especially of the diarrhœa is really a secondary object of treatment. For the vomiting, lavage of the stomach with normal saline is the best treatment, particularly in the early stages, and a poultice may be applied to the epigastrium. Drugs are of little help, but small repeated doses of calomel (*e.g.* $\frac{1}{6}$ grain every hour for six doses) are sometimes useful. Chlorbutol in 1-grain doses may also be used cautiously.

As has already been pointed out, no active steps should be taken to arrest the diarrhœa at the onset. If it continues, however, and seems to be contributing to the exhaustion, one may try to reduce the frequency of the stools. In the early stages, small repeated doses of castor oil are useful for this purpose, and later, when the tongue is clean, bismuth, chalk, catechu and other astringents, as in the case of simple diarrhœa, may be used. A powder composed of 5 grains of bismuth carbonate, with $\frac{1}{8}$th grain each of Dover's powder and calomel, is also a frequent prescription at this stage. Opium should not, however, be given at the outset, and it is best withheld so long as prostration is marked and the temperature high. When prescribed, it may be given in the form of the tincture in the proportion of 1 minim for every year of the child's age. It is specially indicated when the motions are frequent and attended by colic and tenesmus. In cases of the choleraic type, with much vomiting and profuse purging, morphine may be given hypodermically with great advantage. The dose for a child of 1 year is $\frac{1}{30}$th grain, with which $\frac{1}{600}$th grain of atropine may be combined. This may be repeated in an hour if the symptoms have not abated.

"Intestinal antiseptics" are of little help, and may easily be injurious. The best are salicylate of bismuth, salol and resorcinol. If the stools are very watery, nitrate of silver is the most powerful astringent.

After the acuter symptoms have passed off one must return very gradually to ordinary diet. Milk should be given at first malted or fully peptonised and freely diluted with lime water, or condensed or low fat dried milk, or one of the patent foods may be used in place of it. A feed may be given every 4 hours, and water between if the child is thirsty. Any return of the vomiting or diarrhœa must be the signal for again giving up milk in any form. During convalescence change of air and mild iron tonics are of service in restoring the child to complete health. Relapses, which are frequent, must be guarded against with the greatest care.

HILL DIARRHŒA

Definition.—A peculiar form of gastro-intestinal derangement occurring in Europeans living at high altitudes in India, Ceylon and elsewhere during the hot season, characterised by dyspeptic symptoms, abdominal flatulence and the passage of pale-coloured or white, frothy, fluid stools early in the morning.

Ætiology.—The condition occurs in the Himalayan hill stations of India during the rainy season, and the highlands of Ceylon, Europe and South America, at elevations of 6000 feet or over. Europeans of both sexes and all ages are liable, and in some years the condition has affected a large portion of the hill population, as in the Simla epidemic of 1880. The cause has been variously attributed to the mica content of the drinking water, to its bacterial contamination, with resulting infection of the bowel, as well as to a physiological breakdown of the gastro-intestine under conditions of low barometric pressure and high humidity: the latter view is possibly correct.

Pathology.—Little is known either of the clinical pathology or morbid

anatomy of the disease, the nature of which will remain obscure until it has been investigated along biochemical lines, such as has recently been done in sprue.

Symptoms.—The symptoms are flatulence and abdominal distension associated with morning diarrhœa. Defæcation is urgent and generally first occurs about 5 a.m.; subsequently the bowels may be opened four or five times before noon, after which the patient is comfortable. The stools are copious, fluid, pale-coloured or white, frothy, and generally not objectionable in odour. Often the condition is transient, but if it persists considerable loss of weight may ensue. The stools are said to contain an excess of fatty acids, soaps, undigested food remnants and yeasts, while stercobilin as such is either decreased or absent. These findings are similar to those encountered in tropical sprue, and in view of the marked abdominal distension, intestinal flatulence and gaseous nature of the stools, it would appear that, as in tropical sprue, the intestinal breakdown is characterised by defective absorption of certain food elements—especially fat and glucose.

Prognosis.—This is generally quite good; the only danger is that the condition may develop into sprue, and Rogers states that 20 per cent. of his Calcutta cases commenced with hill diarrhœa.

Treatment.—Until more is known regarding the biochemical nature of the gastro-intestinal breakdown, treatment must remain empirical. An initial dose of oleum ricini (min. 240) and tinct. opii. (min. 15), rest, warm clothing and milk diet are generally advised, but probably a high protein, low fat, low carbohydrate diet, such as sprulac, would prove more valuable. Dilute hydrochloric acid in 60 minim doses after food may be tried, and pepsin has also been advocated. Crombie used to give 60 minims of liq. hydrarg. perchlor. 15 minutes after food. Should these measures not suffice the patient must return to the plains.

CŒLIAC DISEASE

Synonyms.—This disease was first described by Gee in 1888 under the title of "The Cœliac Affection." Cheadle redescribed it in 1903 as "Acholia," and Herter in 1908 as "Intestinal Infantilism." It is sometimes spoken of in America as "Chronic Intestinal Indigestion," but in this country the term "Cœliac Disease" is now generally applied to it.

Definition.—A wasting disease of childhood characterised by the passage of large, pale, offensive stools which contain an excess of split fat, and leading to emaciation and arrest of growth; various complications due to avitaminosis may be superadded.

Ætiology.—The cause is unknown. There is no hereditary element; girls are more susceptible than boys, and no social class is exempt. The disease appears to be rarer in the Latin countries than in the Anglo-Saxon and Scandinavian.

Pathology.—There is no characteristic morbid anatomy, the post-mortem changes being attributable to inanition or to intercurrent disease from secondary infection. The bones tend to show changes similar to those of

CŒLIAC DISEASE

Synonyms.—This disease was first described by Gee in 1888 under the title of "The Cœliac Affection." Cheadle redescribed it in 1903 as "Acholia," and Herter in 1908 as "Intestinal Infantilism." It is sometimes spoken of in America as "Chronic Intestinal Indigestion," but in this country the term "Cœliac Disease" is now generally applied to it.

Definition.—A wasting disease of childhood characterised by the passage of large, pale, offensive stools which contain an excess of split fat, and leading to emaciation and arrest of growth; various complications due to avitaminosis may be superadded.

Ætiology.—The cause is unknown. There is no hereditary element; girls are more susceptible than boys, and no social class is exempt. The disease appears to be rarer in the Latin countries than in the Anglo-Saxon and Scandinavian.

Pathology.—There is no characteristic morbid anatomy, the post-mortem changes being attributable to inanition or to intercurrent disease from secondary infection. The bones tend to show changes similar to those of

rickets and the blood chemistry is also similar. The essential pathogeny of the disease appears to be a failure in fat and carbohydrate absorption of obscure causation. The ordinary changes of enteritis are not found.

Symptoms.—The disease begins insidiously between the ninth month and the end of the second year. The child loses appetite, fails to thrive, and has slight diarrhœa. Soon the characteristic stools appear. They are large, but not necessarily frequent, pale, extremely offensive and sometimes frothy and fermenting. On chemical examination they contain from 40 to 60 per cent. of split fat instead of the normal 25 per cent., but the amount of unsplit fat present is not altered. Meanwhile the emaciation progresses, the face being least affected by it and the buttocks most. The abdomen, by contrast, is prominent, doughy and distended. Along with these physical signs there is a change in mentality. The child is often remarkably precocious, but is irritable, hysterical and "difficult," especially during the exacerbations. There is frequently a profound anorexia, and muscular weakness may be extreme.

Complications.—Various deficiency symptoms are apt to appear as the result of avitaminosis induced either by impaired fat absorption or by the character of the diet which treatment demands. Rickets may show itself either early, or, after the age of 7, in the "late" form, with genu valgum as its main sign. Symptoms such as œdema and absence of reflexes may suggest beriberi and have been attributed to deficiency of vitamin B. Scurvy is not uncommon, and attacks of tetany may occur in association with a low blood calcium.

Diagnosis.—At the outset the disease may be impossible to recognise, but when the characteristic stools appear diagnosis is easy. Arrest of growth is of great diagnostic value. The distended abdomen may suggest tuberculosis, especially if distended, atonic bowel with fluid fæces mimics the signs of ascites. Cœliac disease presents many points of resemblance to sprue, but the latter is rare in childhood, and in cœliac disease the blood shows a secondary anæmia and not the megalocytic type characteristic of sprue.

Course and Prognosis.—The disease runs a prolonged course with many ups and downs and is peculiarly prone to relapse. It may last into adult life (cases of "non-tropical sprue" may be examples of unrecovered cœliac disease) but usually tends to recovery before puberty. The mortality may be put down at about 10 per cent., and death, when it occurs, is usually due to intercurrent disease. During the active phases of the disease growth is arrested, and even after recovery the patient may be permanently stunted (intestinal infantilism).

Treatment.—Apart from general hygienic measures treatment is essentially dietetic. A diet high in protein, low in fat, and with no carbohydrate (at the outset at least) is the ideal to aim at. It may consist at first of a dried "protein" milk with the addition of underdone scraped meat, white of egg, broth, jellies, etc. Later, small quantities of fat in the form of bacon and butter are added with carbohydrate mainly in dextrinised form (Mellin's Food, grape-nuts, rusks, crisp toast, etc.). Over-ripe bananas often have a beneficial effect. Care must be taken to supply the necessary vitamins in order to ward off complications. Vitamins A and D may be given as radiostoleum; B, as yeast extract; C, as ascorbic acid, 25 mgm. daily. A small

dose of castor oil should be administered when abdominal distension is troublesome; otherwise there is no indication for drugs.

ROBERT HUTCHISON.
ALAN MONCRIEFF.

IDIOPATHIC STEATORRHŒA

Synonyms.—Adult Cœliac Disease; Non-tropical Sprue; Gee-Herter Disease; Herter-Heubner Disease; Gee-Thaysen Disease.

Definition.—This is the adult form of cœliac disease (see above). With certain very rare exceptions it arises in childhood, though some cases remain unrecognised until adolescence or adult life is reached. The main features are: Fatty stools, with or without diarrhœa, and sometimes with dilatation of the colon; tetany; osteomalacia; anæmia of various types; skin lesions; and frequently infantilism.

Ætiology.—This is unknown. Patients affected have not lived abroad, and the disease cannot be classed with sprue, though resembling it in many respects. The affection is neither familial nor congenital. It is slightly more common in females than in males. The disease has been described in the Scandinavian countries, Germany, Switzerland, France, Great Britain and America.

Pathology.—The underlying disturbance is interference with the total function of the small intestine, and this may be referred to as chronic jejuno-ileal insufficiency. Attempts to demonstrate an anatomical lesion have failed even with the microscope. The symptoms develop in spite of an adequate diet, and the patient starves in the midst of plenty. Deficient absorption of various components of the diet explains many of the signs and symptoms. The fat, although split, cannot be digested and produces steatorrhœa. On a low fat diet, the percentage of total fat in the stools forms on the average more than 25 per cent. of the total weight of the dried fæces; on a normal diet this figure reaches 40 to 60 per cent. The fats are mainly split fats, the figure for neutral fat not exceeding 3 per cent.

Sometimes there is carbohydrate dyspepsia, with production of gas which distends the bowel. This arises from the bacterial hydrolysis of starch following the failure of amylolytic digestion by succus entericus. Sugar is poorly absorbed, and the blood sugar curve after glucose is much flatter than normal. Similarly, proteins are ill absorbed and the blood urea is often below normal. Poor absorption of salts is seen in the low figure for serum calcium, usually 8 mg. per 100 c.c., and the low or normal plasma phosphorus. The height of the plasma phosphatase coincides approximately with the degree of active change in the bones. Calcium balance estimations reveal high figures for fæcal output, and very low figures for urinary output.

Defective absorption of iron is followed by hypochromic anæmia; and megalocytic anæmia may appear, presumably because of failure to utilise the anti-pernicious anæmia factor. Occasionally xerophthalmia and toad-skin appear, proclaiming vitamin-A deficiency. Sore tongue, cheilosis, anosmia and pellagra-like skin result from shortage of the vitamin-B complex. Osteomalacia occurs from deficiency of vitamin D. A tendency to sudden hæmorrhages indicates vitamin-K deficiency. It is associated with

a prolongation of the coagulation time and a reduction in the blood prothrombin concentration.

Symptoms.—The presenting symptom is either diarrhœa, pain in the bones with deformity, or tetany. The stools are bulky and pale, though not always conspicuously frequent. The wasting and distended abdomen so constantly found in children with cœliac disease is not a noticeable feature, even though severe diarrhœa be present. The skin shows a dirty putty-coloured pallor, and the hair is fine, mud-coloured and liable to turn grey at an early age. In 50 per cent. of cases a skin eruption is present on the limbs, and to a lesser extent on the trunk. The lesions are moist red abraded areas with scaly brown pigmented borders, resembling pellagra. In 60 per cent. of cases the fingers are clubbed. By means of the slit-lamp small flaky opacities are to be seen in the various layers of the lens. They never progress sufficiently to interfere with vision.

All cases show some degree of skeletal deformity, including genu valgum, bending and bowing of the bones, distortion of the pelvis, beading of the ribs and spontaneous fracture. In 60 per cent. of cases there is dwarfism, but this is not necessarily associated with mental or sexual infantilism. The male genitalia are poorly developed, and the voice high pitched. In women the onset of menstruation is delayed. The disease is usually accompanied by sterility, but should pregnancy occur there is often an acute exacerbation of symptoms. Pelvic deformity may interfere with the normal course of labour. Tetany occurs in almost all cases. Seventy per cent. of patients describe recurrent attacks of tinglings in the fingers and hands, followed by carpo-pedal spasms. These interfere with writing, piano-playing, and even with walking. In 30 per cent. of patients tetany is latent only, its presence being detected on eliciting the Trousseau or the Chvostek signs.

The blood picture is either normal or shows (i) hypochromic anæmia, (ii) hyperchromic megalocytic anæmia, or (iii) erythroblastic anæmia. This polymorphic character of the blood changes is frequently found when anæmia is associated with gastro-intestinal lesions. Achlorhydria is uncommon, occurring in less than 20 per cent. of all cases and in only one-third of those with hyperchromic megalocytic anæmia. This anæmia is therefore not Addisonian pernicious anæmia, a fact confirmed by the observation that it yields to treatment by vitamin-B concentrates. Hæmorrhagic phenomena are rare, even in cases treated for a long time by means of a low-fat diet. They include hæmatemesis, melæna, epistaxis, menorrhagia, hæmaturia, hæmarthroses, subcutaneous hæmatomata and intractable bleeding from wounds. Scurvy is very rarely seen.

In long-standing cases opaque enema examination shows dilatation of the colon, and sometimes this assumes the proportions of megacolon. In all cases radiographs of the skeleton reveal osteoporosis, and if the epiphyses have not united the translucent cup-like metaphyses of rickets are present. Many cases show fine transverse lines of increased density of bone immediately to the diaphyseal side of the metaphyses of the long bones. Distortion of the limbs, spine and pelvis are common.

Diagnosis.—A denial of residence in a country where sprue is endemic is enough to rule out that disease. Chronic jejuno-ileal insufficiency has been observed in gastro-jejuno-colic fistula. Here the history of previous gastro-enterostomy simplifies the diagnosis. Rarely the syndrome of steatorrhœa,

tetany and megalocytic anæmia is produced by diseases which cause obstruction of the lacteals. These include tuberculosis, lymphogranuloma and lymphosarcoma affecting the mesenteric lymph nodes.

Prognosis.—The results of treatment are disappointing in the adolescent and adult cases compared to what is seen in children. Some respond satisfactorily and remain well under treatment. In the majority all that is accomplished is the alleviation of one or more symptoms and the temporary onset of the downward progress. It is none the less gratifying to see the great improvement in the anæmia of many of the cases, and the recovery from the pain and disability of osteomalacia in others. Often there is a great change for the better in the mental outlook of the dwarfed, crippled, anæmic patient as he is gradually relieved of his disabilities. Unfortunately one group of symptoms and signs may clear up completely, and yet the patient may die in inanition. Thus extensive, moist, red excoriated skin lesions may heal under treatment with marmite, yet relapses of diarrhœa and tetany may result in the death of the patient, the skin remaining normal.

Treatment.—This presents great difficulties. While nothing can be done to remedy the primary defect much care can be given to mitigate as far as possible its consequences. The steatorrhœa must be controlled by a low-fat diet. No patient with this disease can be given the amount of fat found in the average diet without risking the occurrence of diarrhœa. The diet should be high in calcium content. The best way to secure a low-fat high-calcium intake is to use skimmed milk and preparations of calcium caseinate, such as casec or laitproto. The items of such a diet include meat, chicken, bread, a scraping of butter, oatmeal, potato, rice, tea, sugar, skimmed milk, cheese, jam, cabbage, apple, banana and tomato. These items can be arranged as follows: carbohydrate 325 gm., protein 90 gm., fat 30 gm. and calcium 2 gm. Sometimes gas formation from carbohydrate fermentation is a prominent symptom, and then the intake of starch should be strictly controlled, and the administration of diastase may be useful.

When tetany occurs, calcium lactate should be given fasting in doses of 5 gm. three times a day. In emergency 20 c.c. of a 5 per cent. solution of calcium chloride or gluconate may be injected into a vein, and if administered very slowly no ill effects are produced. Vitamin D should be given in every case in which there are clinical or radiographic signs of rickets, osteomalacia or osteoporosis. General ultra-violet irradiation is also of value. These measures may relieve bone pain, though any relapse of diarrhœa is liable to interfere with this good effect. Cod-liver oil, or any other form of vitamin D in an oily medium, is contra-indicated in view of the defective fat absorption. Vitamin D should be given in a solid medium—calciferol tablets two or more daily.

Treatment of the anæmia must depend upon examination of the blood. When it is hypochromic or erythroblastic, large doses of iron should be prescribed until the hæmoglobin figure reaches normal. This usually occurs with 30 gr. of Blaud's pill or 6 gr. of ferrous chloride three times a day. When hyperchromic megalocytic anæmia is present, injections of an active liver extract should be repeated until the red cell count remains at 5 millions. The initial dose may be 1 to 4 c.c. daily, and the maintenance dose is often 1 c.c. per week. Marmite by mouth may be used instead of liver extract, as much as 12 gm. daily usually being required. Whatever the form of the

anæmia, it is essential to remember the importance of adequate dosage. For one week in each month a prophylactic dose of vitamin K or its derivative should be given by mouth. A suitable dose is 30 mg. of methyl-naphthoquinone. If hypoprothrombinæmia has already led to hæmorrhage the vitamin or its synthetic analogue should be administered by injection, double the above doses being used.

Orthopædic treatment includes splinting or even osteotomy to correct deformities, such as genu valgum. A cork sole may be necessary, and kyphosis may demand the use of a spinal jacket. The pelvic deformity may necessitate Cæsarean section.

DONALD HUNTER.

SPRUE

Synonyms.—Cochin-China Diarrhœa; Psilosis; Ceylon Sore Mouth, etc.

Definition.—Sprue is a disease of unknown ætiology involving the gastro-intestinal tract, characterised by defects in gastric secretion and inability to absorb adequately fat, glucose, calcium and sometimes vitamins as well. Typically there is an apyrexial, morning diarrhœa with bulky, pale, gaseous, fatty stools, sore tongue, megalocytic, anæmia, asthenia and wasting.

Ætiology.—The disease is mainly confined to the tropics and subtropics, being especially common in parts of India (Bombay), China and Cochin-China, also in Ceylon, Java, the Federated Malay States and Porto Rico in the West Indies. Adult Europeans and people of mixed European blood living in endemic areas are prone to the disease. Except in Porto Rico, the native population is rarely affected. Both sexes are susceptible, but it rarely affects people under 20 years of age. A hot, damp climate, especially on the seaboard, favours its development, while certain bungalows enjoy an unsavoury reputation in this regard. Various theories have been suggested to explain its ætiology. The first infective agent was thought to be *Strongyloides intestinalis*. Later, Ashford and others held it to be a moniliasis of the digestive tract due to *Monilia psilosis*, but the fungoid theory is now being generally abandoned. Scott suggested that there was a metabolic disturbance, resulting in a decreased ionic calcium due to parathyroid involvement. Elders regards sprue as a primary deficiency disease due to lack of vitamins A and B and amino acids, while Castle and his colleagues attribute it to dietary deficiency, *i.e.* an extrinsic factor contained in meat, eggs and whole germ. The difficulty in accepting such a view is the epidemiological fact that sprue often affects the best-fed people in the community, and that, in places other than Porto Rico, people living on a diet deficient in animal protein develop tropical macrocytic anæmia. Finally, the conception of sprue as a primary physiological breakdown, due to climatic and other factors, does not explain its patchy geographical distribution, nor its onset many years after people have left the tropics. Deranged intestinal absorption is the fundamental basis of the sprue syndrome, and until more is known concerning the chemical factors controlling, or involved in, the absorption of such food elements as glucose, fat and calcium, the problem of sprue is likely to remain unsolved. If sprue be a primary deficiency

disease, the deficiency factor must be some unknown vitamin which controls or plays some important rôle in the processes involved in intestinal absorption.

Pathology.—*Morbid anatomy.*—At autopsy the essential lesions consist of an absence of fat, muscular wasting, a small heart, general atrophy of the viscera consequent on malnutrition, a megaloblastic hyperplasia of the red marrow of variable intensity, and atrophic changes in the tongue.

Clinical pathology.—The anæmia, which is by no means invariably present in the early stages, is megalocytic in type, resembling that seen in pernicious anæmia. The Price-Jones curve is also similar. The colour index is usually 1·0 or higher. The blood picture shows numerous megalocytes associated with anisocytosis and poikilocytosis, and in the severer cases polychromasia, basophilic stippling and occasional normoblasts may be observed; megaloblasts are rare. Hypochlorhydria or achlorhydria is common, but 75 per cent. of cases respond to histamine by an increase in HCl secretion. Evidence is accumulating that the megalocytic anæmia has a gastrogenous origin due to defective production of Castle's factor. The total fæcal fat is definitely increased (30 to 70 per cent.), but splitting is adequate. The glucose tolerance test frequently shows a flat type of curve, or one presenting a retarded rise due to malabsorption, while the blood calcium is decreased for the same reason. The blood bilirubin is rarely increased to the extent seen in pernicious anæmia. Malabsorption of fat accounts for the excessively fatty stool, while fermentation of glucose within the lumen of the bowel, consequent on defective absorption, underlies its acid and gaseous characteristics. The pallor of the stool is due to the transformation of stercobilin into colourless leucobilin.

Symptoms.—The incubation period is unknown, but patients have occasionally developed sprue within a few months of arriving in an endemic area. Hill diarrhœa sometimes passes into sprue. Often the onset is insidious with (1) loss of energy, dyspepsia and flatulence; (2) rapid loss of weight; (3) sore tongue or buccal aphthæ; (4) diarrhœa or looseness of the bowels, especially in the early morning. It may be months before the bulky, pale, acid, frothy stools reveal the true nature of the malady. Apyrexia is the rule, and frequently the temperature is subnormal. Once seen, the fully developed picture of sprue makes an indelible impression. Such a patient is asthenic, emaciated, mentally taciturn and often severely anæmic; the skin is parched, wrinkled and often pigmented over the forehead and malar eminences, while the nails are ridged and brittle; the tongue, which is invariably clean, may be patchily inflamed, ulcerated and atrophic, while the thin abdominal parietes scantily protect the attenuated coils of gas-distended bowel visible beneath. Physical examination also often reveals a decrease in the area of the liver dullness: this is partly attributable to atrophy and partly to intestinal distension. Hæmic murmurs may be heard over the heart, which is small, while both systolic and diastolic blood pressure is invariably lowered. On questioning such a patient he often complains of sore tongue and aphthous ulcers made worse by spiced and hot foods, of characteristic early morning stools, and of abdominal distension and intestinal flatulence generally most marked towards evening and often related to the carbohydrate intake. Œdema of the feet, cramps and tetany, associated with Chvostek's and Trousseau's signs, may occasionally be observed.

Paræsthesias are often complained of, and tendon reflexes, especially the knee-jerks, may be absent.

Complications.—Pyrexia should always arouse suspicion of some intercurrent infection or complication, the commonest of which is a *B. coli* infection of the urinary tract. Often this infection is unassociated with fever, and in every case of sprue the urine should be examined for pus cells and cultured for bacteria. Unlike pernicious anæmia, subacute combined degeneration of the cord is not encountered. Neuritic features are not uncommon, tetany with hypocalcæmia occurs in about 2 per cent. of cases, and occasionally purpuric skin eruptions are seen. Anal fissure and hæmorrhoids may develop, while venous thrombosis, eczema and pneumonia are occasionally encountered. Ulcers in the small intestine have been noted in a few cases, and perforation of the bowel has been recorded.

Course.—Sprue is a very chronic disease, showing spontaneous remission and exacerbations, with a tendency to natural cure if the patient leaves the tropics. The causes of death in inadequately treated cases are malnutrition, anæmia and intercurrent disease.

Diagnosis.—The well-established case presents little difficulty, but in the initial stages and in atypical cases considerable clinical experience may be required to make a diagnosis. The differential diagnosis includes pellagra, pernicious anæmia, tropical macrocytic anæmia, gastric carcinoma, gastro-colic fistula, tuberculous adenitis and lymph adenoma involving the mesenteric glands, Addison's disease, chronic pancreatitis and carcinoma of the pancreas. Biochemical and radiological investigations may be essential for their differentiation.

Prognosis.—This largely depends on the co-operation of the patient and the institution of modern treatment which has greatly increased the expectancy of life. In the absence of intercurrent infection, patients recover, provided they are correctly treated, and it is permissible to let them return to the tropics if they are under 55 years of age, otherwise healthy and have been free from symptoms on a normal diet for 6 months without treatment.

Treatment.—The essentials of treatment are: (1) The institution of alimentary rest by appropriate dietary; (2) the treatment of megalocytic anæmia if present; (3) the reinforcement of demonstrable deficiencies by such means as hydrochloric acid, calcium salts, etc. Both in the primary attack and during relapses these asthenic, poorly nourished patients must be put to bed for 5 to 8 weeks under conditions that ensure mental as well as physical rest, while in Europe warmth and the avoidance of chill are essential. (1) *Dietary.*—Many different diets have been advocated, the best known being Manson's milk treatment. The feeds were given in small quantities 2-hourly, commencing with 3½ and increasing gradually up to 7 pints daily. Van den Burg advocated large quantities of pulpy fruit free from acidity, coarse seeds and fibres; ripe bananas, bael fruit, papaya and strawberries are popular, the latter being particularly favoured in Europe. The red meat diet of Cantlie commenced with 2-ounce feeds of lean, minced, underdone steak, which were gradually increased until 1½ to 2 lb. were taken daily. As a result of observations on the defective absorption of fat and carbohydrate in this disease, Fairley introduced graded high protein, low fat, low carbohydrate diets, the ratios of the three fundamental foodstuffs being as

1·0 : 0·3 : 1·3 and the energy values varying from 600 to 3000 calories. Red meat is the main source of protein advocated, but more recently a defatted dried milk (sprulac), with similar food ratios has become available. A convalescent high protein diet with fruit and vegetables is generally permitted in the fifth or sixth week, and subsequently the amount of fat and carbohydrate is gradually increased. (2) *Anæmia.*—The anæmia of sprue is megalocytic in type and almost invariably responds to adequate dosage of liver extract *per os*, provided appropriate dietetic measures are simultaneously instituted to control the diarrhœa. Maximal reticulocytosis occurs about the ninth day and the blood regenerates at a rate comparable to pernicious anæmia. For the first month dried extract, equivalent to 1½ lb. of fresh liver daily, should be given ; generally in the second month the dosage can be reduced to the equivalent of 1 lb. daily, and in the third month to ½ lb. In chronic cases, which have repeatedly relapsed, a maintenance dose of ½ lb. liver daily may be advisable for 3 to 6 months after the blood has been restored to normal. Very rarely are refractory cases encountered in which reticulocytosis is submaximal and blood regeneration inadequate. Here oral treatment can be reinforced by parenteral liver injections, hepastab (4 c.c. daily), pernæmon forte (4 c.c. daily), campolon (6 c.c. daily), for a period of 2 to 3 weeks. In such cases intercurrent infection should be sought for. Unfortunately marmite, even in a dosage of 240 grains daily, is not a satisfactory substitute for liver, since diarrhœa may be increased and the reticulocyte response is generally submaximal and associated with little or no improvement in the anæmia ; exceptionally cases respond dramatically with maximal reticulocytosis and rapid blood regeneration. Blood transfusion is rarely necessary nowadays, its only indication being to tide a dangerously anæmic patient temporarily over the latent interval before a response to liver extract is obtainable. The anæmia in sprue is generally orthochromic or hyperchromic, but in those rare cases where hypochromia is present, or in which there is an undue lag in the production of hæmoglobin following liver extract therapy, intercurrent infection or intestinal ulceration should be suspected. Full doses of iron should, of course, be prescribed. (3) *Treatment of Demonstrable Deficiencies.*—Where acid secretion is defective, acid. hydrochlor. dil. in doses of 60 minims in diluted orange juice should be administered thrice daily after food. Tetany, with hypocalcæmia, calls for the administration of calcium lactate (grains 30 thrice daily) ; even more important is a diet low in fat, since calcium cannot be satisfactorily absorbed when there is an excess of fat in the stools. Vitamin D in the form of calciferol or ultraviolet radiation may also be prescribed as an accessory measure, but is rarely necessary.

B. coli infections of the urinary tract respond satisfactorily to sulphonamide therapy. Proseptasine, in a dosage of 1·0 g. (2 tablets) every eight hours from 7 to 10 days, is well tolerated and generally eradicates the infection.

Once the sprue patient has regained his health he should continue with a well-balanced diet adequate in vitamins and protein, avoiding alcohol, rich, spiced and sugary foods and condiments. Aperients should be taken with caution, and care exercised to avoid chill and respiratory infection. Sprue relapses may recur after many intervening years of perfect health.

G. Carmichael Low.
N. Hamilton Fairley.

MUCO-MEMBRANOUS COLIC

Definition.—In nervous individuals constipation is sometimes associated with the constant or intermittent passage of membranes of coagulated mucus and with attacks of pain, the condition being known as muco-membranous colic. This name is preferable to muco-membranous colitis, as no true inflammation of the colon is present.

Ætiology.—Muco-membranous colic was formerly a common condition in women of the educated classes, and was occasionally also observed in men. For no obvious reason its incidence has greatly diminished since 1914, and well-marked cases are now rarely seen.

Pathology.—Two predisposing factors are invariably present—constipation and an abnormally irritable nervous system. Retention of fæces in an individual with an abnormally irritable nervous system may result in reflex over-activity of the motor and secretory fibres of the colon, leading respectively to painful spasm and to excessive secretion of mucus. The former may occur alone; the resulting spasm of the colon is analogous to pure spasmodic asthma, and, in contrast with muco-membranous colic, it is still comparatively common (p. 617). If the mucus is retained sufficiently long, coagulation takes place and a membrane forms. This is analogous with the formation of Curschmann's spirals in asthma. The mucus contains no pus cells or red corpuscles and the sigmoidoscope reveals a perfectly normal mucous membrane. Some catarrh may be present if the condition has been injudiciously treated with irritating purgatives or injections. In rare cases of allergic origin large numbers of eosinophil cells, sometimes with red blood corpuscles, are present in the mucus.

Symptoms.—In some cases the patient constantly suffers from abdominal discomfort and passes membranes. In others definite attacks, which are often emotional in origin, occur at intervals of weeks or months; the pain may be confined to the attacks, or there may be abdominal discomfort in the intervals. It is, however, not uncommon for the presence of membranes in the stools to be the only symptom.

The pain is situated most frequently in the left flank and iliac fossa and just above the pubes; at the same time the descending and iliac colon are often tender and can be felt as a contracted cord, in which scybala can sometimes be distinguished. Less frequently there is pain and tenderness in the cæcum and ascending colon, which are felt to be more firmly contracted than usual; the condition may then closely simulate appendicitis, but no relief follows appendicectomy. The passage of fæces and membranes or of the latter alone, whether spontaneously or as the result of treatment, generally gives temporary relief.

The constipation present in the intervals becomes much more severe during an attack. The stools consist of hard, small scybala, which may occasionally be moulded into thin or flat pieces as a result of anal spasm.

The mucus is passed as very thin membranous shreds, which may form long tubular casts of the colon, which are sometimes rolled into a ball. The mucus may be transparent like ordinary mucus or opaque like fibrin and grey-white, but it is often stained by fæces and rarely by blood. The membranes

may be passed alone or with scybala. They are sometimes mistaken for shreds of mucous membrane and for tape-worms.

Various symptoms resulting from the associated neurasthenia or anxiety neurosis are generally present, and the patient always tends to become depressed and hypochondriacal.

Intestinal Sand.—The passage of intestinal sand is generally associated with muco-membranous colic. Small quantities of sand, which would otherwise escape detection, can often be discovered by running water on the fæces until the greater part is washed away. True intestinal sand must be distinguished from the sand formed of wood-cells, which is sometimes passed by individuals who have eaten a large quantity of pears or bananas. It is composed of pale yellow or reddish-brown granules, irregular in shape and never crystalline. Their most characteristic constituents are the insoluble calcium soaps of palmitic and stearic acids; an approximately equal quantity of calcium phosphate is also present.

Prognosis.—Muco-membranous colic is a very chronic condition. If treatment is begun at an early stage recovery generally follows, but when it has been present for many years the pasage of membranes is likely to persist even if the accompanying symptoms disappear as a result of treatment.

Treatment.—A patient suffering from muco-membranous colic should be treated with the object of removing the two underlying factors—the abnormal condition of the nervous system and the constipation. The former calls for simple psychotherapy. The patient should be discouraged from making minute investigations of his stools; she should be told to be satisfied if she feels better without looking to see how much mucus is passed. She may feel perfectly well in spite of the presence of mucus; but she will often remain so only as long as she is unaware that she is passing it.

The constipation requires treatment by diet, massage, drugs and enemata. The best results are generally obtained with a generous mixed diet containing a plentiful supply of those articles which have already been described as useful in uncomplicated constipation on account of their chemically stimulating properties, but excluding raw vegetables in salads and pickles, fibrous vegetables such as celery, and the skins and pips of fruit. Mustard, pepper and spices of all kinds should be prohibited. Smoking should be restricted, and in severe cases should be entirely prohibited.

At the commencement of treatment any accumulation of fæces in the colon must be removed. This can best be done by an enema of 6 fluid ounces of paraffin given in the evening and retained during the night. Once the colon is empty, the reaccumulation of fæces can often be prevented by the administration of liquid paraffin and isogel or coreine in order to soften the stools. If this does not result in the passage of a satisfactory stool each day, the further treatment depends upon whether the stasis is in the proximal part of the colon, in which case a mild aperient, such as infusion of senna pods, is required, or in the pelvic colon, when treatment by paraffin enemata without aperients is indicated.

As in the case of uncomplicated colon spasm, belladonna is the most useful drug for combating the pain; small doses of bromide may also be given to diminish the irritable condition of the nervous system.

Local treatment of the mucous membrane of the colon by Plombières douches should be used only in the exceptional cases in which other treatment

has failed to give relief. As the patients are always self-centred, it is of the utmost importance to avoid encouraging them to concentrate upon their bowels and their excreta by irrigating the colon unless this is absolutely necessary. Intestinal lavage can be given at home; but it is generally more effective at one of the spas, such as Harrogate, Llandrindod Wells, Bath or Buxton, at which there are special facilities for carrying it out with the natural waters. Normal saline solution should be used if the treatment is given at home, and injections of soap and water, antiseptics and astringents should be avoided, as they tend to aggravate the condition by irritating the mucous membrane.

INTESTINAL CARBOHYDRATE DYSPEPSIA

Definition.—Intestinal carbohydrate dyspepsia is a condition in which discomfort results from the presence of excess of gas in the colon owing to the fermentation of carbohydrates which have escaped digestion in the small intestines.

Pathology.—Under normal conditions starch is digested by the ptyalin of the saliva and the amylopsin of the pancreatic juice. The ptyalin is the less important, as it is rapidly destroyed by the first trace of free hydrochloric acid with which it comes into contact in the stomach. It was formerly believed that the starch in vegetable food could be digested only when the cellulose had been broken up by cooking, or, if eaten raw, after it had been dissolved by the action of a hypothetical cellulose-splitting ferment in the small intestine or of bacteria in the colon. It is now known that the cellulose walls of vegetable cells are not broken by cooking, a cellulose-splitting ferment does not exist in the human alimentary tract, and bacteria do not normally take any part in the digestion of carbohydrates, which is almost confined to the upper part of the small intestine. Ferments penetrate the unbroken walls of vegetable cells and digest the starch within them, the sugars produced passing out into the surrounding media, from which, owing to the absence of bacteria, they are absorbed without undergoing fermentation.

Normally starch is completely digested in the upper part of the small intestines so that very little reaches the terminal ileum and none reaches the cæcum. When the rate of passage through the small intestines is excessive, there is time for free starch and starch in cells with broken walls to be digested, but the starch in intact cells reaches the terminal ileum and cæcum unaltered. Here the amylopsin penetrates the cells, and the sugars pass into the surrounding media, where they are attacked by bacteria, which are present in very large numbers, and undergo fermentation before there is time for much absorption to take place. The symptoms of intestinal carbohydrate dyspepsia are caused by the carbon dioxide and acetic and butyric acids produced by this fermentation.

In most cases of intestinal carbohydrate dyspepsia there is a history of food-poisoning or of some intestinal infection which has caused enteritis. The latter may still be present, but more commonly it has given place to a functional irritability of the small intestine, which results in excessive motor activity.

Symptoms.—The chief symptom of intestinal carbohydrate dyspepsia is a widespread feeling of discomfort and fullness in the lower part of the abdomen, caused by distension of the colon with carbon dioxide. During the day gas often collects in the splenic flexure, which is the highest point in the colon: the discomfort produced in this way may be mistaken by the patient for gastric flatulence, and aerophagy often results from his attempt to relieve himself by belching. During the night the gas passes to the rectum, which is then as high as any other part of the colon; consequently the greater part is passed during the night and on waking in the morning. The discomfort is generally increased by meals as a result of exaggeration of the gastro-colic reflex. It is often greatest during the night, and is a very common cause of insomnia, which can be cured at once by a suitable diet. The excess of gas produces borborygmi, the noise of which may itself be enough to keep a patient awake. The irritation of the bowel caused by the gas and organic acids may cause spasm; the patient then complains of acute pain. Excessive quantities of odourless flatus are passed, and some relief is always felt after its escape.

The abnormally rapid passage of the chyme through the small intestine can be demonstrated with the X-rays, even when the irritation of the colon is insufficient to cause any diarrhœa, and the X-rays show no change in the normal rate of passage through the colon. In severe cases attacks of mild diarrhœa are common, much gas being always passed with the stools, which are acid and have an unpleasant sour, but not putrefactive, odour when they are liquid. The diarrhœic stools always contain an obvious excess of undigested vegetable matter, and bubbles of gas may continue to form as a result of fermentation of the undigested starch they contain.

A fresh stool should be examined whilst the patient is on his usual diet. Microscopical examination reveals the presence of large numbers of starch granules, which are still within their cellulose envelopes and stain blue with iodine. Few or none are present in normal fæces. In contrast with the stools in pancreatic achylia there is no excess of fat or of striated muscle-fibres. The normal enterococci of the colon are present in considerable excess, but the number of *B. coli* is not increased and no pathogenic organisms are found. On giving a starch-free diet the excess of enterococci rapidly disappears; it is clear, therefore, that the enterococcal excess is not the cause of the condition, but is the result of the excellent culture medium afforded by the excess of carbohydrates present in the colon. If a small quantity of fresh fæces is mixed with water and incubated for 24 hours, any gas given off being collected, the fermentation which has been taking place in the colon in intestinal carbohydrate dyspepsia continues *in vitro*. A considerable quantity of odourless gas is evolved and the fæces become very acid, whereas no gas is evolved from normal stools. If the examination of a stool is delayed for 6 hours or more, all undigested starch may have disappeared and no further gas is evolved on incubation. In the much less common putrefactive diarrhœa, which is due to insufficient digestion of meat, a smaller quantity of foul gas is evolved and the fæces become strongly alkaline.

Treatment.—All root vegetables (potatoes, carrots, onions, beetroot, artichokes, parsnips), green peas and lentils, bananas, rice, tapioca and sago, and porridge are prohibited. Bread, toast and biscuits, and puddings containing starch are allowed in small quantities, and there is no need to restrict

the intake of sugar. If diarrhœa is present, it is necessary to exclude all vegetables and fruit, whether cooked or raw. Within a week the excess of enterococci disappears from the stools, which no longer ferment on incubation. It may be necessary to avoid potatoes and other root vegetables for a considerable period and sometimes permanently.

If a diastatic ferment of vegetable origin is taken with each meal, less restriction in diet is required, as in contrast with the amylopsin of pancreatic preparations it is very slowly destroyed by the gastric juice so that more digestion of starch can occur in the stomach.

A tablespoonful of powdered activated charcoal may be given in a small quantity of water morning and evening to absorb any gas which is still produced, but this should be unnecessary if a sufficiently strict diet is ordered. It is much better to prevent the production of gas than to provide for its absorption, as the condition can be permanently cured only by curing the irritable condition of the small intestine, which is aggravated by the mechanical irritation of undigested vegetable matter and the chemical irritation of the products of bacterial activity on starch.

In severe cases, especially those associated with diarrhœa, excess of gas may still be passed in spite of a strict diet and the use of vegetable diastase and charcoal. This can generally be overcome by giving sufficient codeine to reduce the rapid passage through the small intestine to the normal. A dose of $\frac{1}{4}$ grain of codeine phosphate given three times a day before meals with 5 minims of tincture of belladonna is generally sufficient.

As the excess of enterococci present is a result and not the cause of the condition, vaccine treatment is quite useless. I have seen many patients rapidly cured by diet alone after having undergone many months of treatment by inoculation without the slightest benefit. Colonic lavage, which is almost as popular a treatment, is, of course, equally futile.

ORGANIC DISEASES OF THE INTESTINES

ENTERITIS

Acute Enteritis

Acute enteritis forms part of the picture in most cases of acute food poisoning. Acute gastritis may be present alone when vomiting is severe; more commonly gastro-enteritis occurs with diarrhœa with or without vomiting. The poison is generally so diluted when the colon is reached and its evacuation is so rapid that the colon escapes and gastro-entero-colitis is consequently rare. Acute enteritis may also accompany the gastritis of acute infections, such as gastric influenza; in such cases there is diarrhœa as well as vomiting. If the affected individual happens to be one of the 10 per cent. of normal people with hypochlorhydria, the gastritis is likely to lead to achlorhydria, to which the symptoms caused by the enteritis are often erroneously ascribed.

Chronic Enteritis

Chronic enteritis is a common sequel of acute gastro-enteritis caused by food poisoning and acute infections. It may follow infestation with worms, especially tapeworms. It is frequently caused by indigestible food, especially among people who take excess of "roughage" in the mistaken belief that it is good for their health. The small intestines are often irritated by food which reaches them without undergoing the normal preparation in the stomach in achlorhydria and after gastro-jejunostomy and partial gastrectomy. Chronic enteritis is frequently caused by irritation produced by the habitual use of aperients, psyllium seeds and drugs such as arsenic. The loss of the antiseptic acid barrier of the gastric juice in achlorhydria may lead to infection of the small intestines by swallowed bacteria when oral and naso-pharyngeal sepsis is present. Lastly, the stasis which results from chronic small intestine obstruction leads to a great increase in bacterial activity with the production of chemical irritants which cause severe enteritis. This explains why diarrhœa is commonly present instead of constipation in chronic obstruction of the small intestine.

As the chief symptom of enteritis is diarrhœa, the diagnosis and treatment of which are considered on pp. 625, 627, it is unnecessary to give a separate description here.

REGIONAL ILEITIS

Synonym.—Crohn's Disease.

Ætiology.—Regional ileitis is by no means rare. It occurs between the ages of 4 and 40 and is most common in young adults. Males are more often affected than females.

Morbid Anatomy.—The terminal part of the ileum is generally first involved. The disease may spread into the cæcum, and any part of the small intestine and colon may be attacked. The mucous membrane is inflamed and eventually ulcerates, and all the coats of the affected segment become thick, œdematous and rigid. Active inflammation is followed by fibrosis, and the lumen of the rigid bowel becomes progressively more narrowed. The mesentery is thickened and the lymphatic glands are enlarged. Adjacent parts of the bowel adhere together and fistulæ form between them and occasionally open on the surface of the abdomen. Microscopically acute, subacute and chronic inflammation are found with giant cells, so that the appearance closely simulates tuberculosis, with which it has generally been confused in the past. But tubercle bacilli are never found in the wall or lumen of the bowel, and animals inoculated with the tissue never develop tuberculosis. The condition is probably infective, but nothing is known as to the nature of the infection.

Symptoms.—The symptoms are those of progressive small intestine obstruction. The patient complains of attacks of colicky pain of gradually increasing severity and frequence round the umbilicus and in the right lower quadrant of the abdomen, the whole of which is distended with gas. The attacks may be associated with watery diarrhœa and occasional vomiting, but constipation is often present in the intervals. The stools always

contain occult blood; when they are loose, shreds of mucus are present.

The affected segment of the ileum may form a sausage-shaped tumour, which can be felt in the right iliac fossa.

Mild pyrexia with slight polymorphonuclear leucocytosis is often present. After a time anorexia develops, and the patient loses weight and becomes anæmic. Occasionally, general symptoms such as lassitude and loss in weight may precede the intestinal symptoms by some months.

An X-ray examination should be made hourly from 1 to 6 hours after an opaque meal. In addition to the evidence of small intestine obstruction afforded by the presence of loops of dilated bowel containing fluid and gas, filling defects in the terminal ileum and sometimes in the cæcum may be seen. Most characteristic is the "string sign"—a thin, irregular linear shadow passing from dilated coils of ileum through the filling defect to the cæcum. A better view of the terminal ileum is sometimes obtained after a barium enema, which runs through the incompetent ileo-cæcal sphincter.

Diagnosis.—Pain in the right lower quadrant of the abdomen associated with distension, local tenderness, and possibly a tumour and pyrexia should always raise a suspicion of regional ileitis in addition to subacute appendicitis, ileo-cæcal tuberculosis, carcinoma and, when fistulæ are present, actinomycosis.

Treatment.—The affected segment of bowel should be excised. Simple short-circuiting is generally insufficient, as the disease tends to spread in both directions if it is not eradicated. Short-circuiting is, however, required when extensive lymphatic involvement at the base of the mesentery makes excision impossible and as a preliminary operation when fistulæ are present.

COLITIS

Inflammation of the colon may be general or localised to one segment. Thus inflammation of the cæcum (typhlitis), cæcum and ascending colon, pelvic colon, rectum (proctitis), or pelvic colon and rectum (pelvi-rectal colitis) may occur alone, but except in the case of the two last, localisation is rarely absolute.

Although enteritis frequently causes secondary colitis, the reverse is very rare, as infective and irritating material from the ileum must pass along the colon before it is evacuated, whereas the ileo-cæcal sphincter prevents the spread of infection from the cæcum to the ileum.

The inflammation is generally limited to the mucous membrane and submucous tissue, but it occasionally involves the deeper tissues and may spread to the peritoneum (pericolitis). The inflammation may be catarrhal or ulcerative, and chronic or acute.

The term *mucous colitis* should be abandoned, as mucus is passed in all forms of colitis; moreover, most cases so diagnosed are not suffering from colitis at all, the excess of mucus being the response of the mucous membrane of the normal intestines to irritation by purgatives or of that of the pelvic colon and rectum to irritation by scybala. The term *muco-membranous colitis* should also be replaced by muco-membranous colic, as it is a functional condition and not a form of colitis at all (p. 642).

Acute Catarrhal Colitis

Ætiology.—Acute catarrhal colitis occurs most frequently as a result of food poisoning, either alone or associated with acute gastritis and enteritis. It may also be a symptom of specific fevers and various toxæmias, especially uræmia.

Symptoms.—The chief symptom is diarrhœa, the stools being frequent, fluid and offensive; they contain mucus, sometimes traces of blood, but no excess of food residue unless the small intestine is simultaneously affected. Abdominal discomfort is present, and paroxysms of colicky pain are frequent. In severe cases there may be well-marked general symptoms with a high temperature and a rapid pulse. As a rule the condition rapidly improves, but it may develop into chronic colitis.

Treatment.—The treatment is the same as that for Acute Diarrhœa (p. 627).

Chronic Catarrhal Colitis

Ætiology.—The most common cause of chronic catarrhal colitis is the habitual use of purgatives, which are frequently taken even in the absence of constipation. Infection of the bowels with pathogenic organisms, introduced in the food or water or coming from some septic focus in the mouth, pharynx or appendix, may cause a chronic infective, catarrhal colitis, which may also be the sequel of an attack of acute colitis or the colitis of some specific infection, such as amœbic or bacillary dysentery.

Symptoms.—Diffuse discomfort and a sensation of fullness are commonly present in the lower part of the abdomen. Slight attacks of colic may occur, but in many cases there is no actual pain. The abdomen is often somewhat distended and tender. The discomfort is generally worse after meals and is relieved if the bowels are well opened. In infective cases and those following an attack of acute colitis, diarrhœa is generally present, mucus and occasionally traces of blood being found in the fluid stools, but there is no excess of food residue unless enteritis is also present.

The presence of mucus in the stools is often regarded as sufficient evidence to prove that colitis is present. But it is a function of the healthy mucous membrane to secrete mucus to protect itself against mechanical and chemical irritants. Consequently the unformed, clear mucus passed with hard fæces in constipation, and especially in dyschezia, does not indicate that colitis or proctitis is present, and the same is true of the mucus passed with fluid stools, when irritating aperients have been taken. Only if mucus is passed with soft fæces when no purgative has been given can it be regarded as of any diagnostic importance. On the other hand, pus and red blood corpuscles generally indicate the presence of either ulcerative colitis or carcinoma, though the possibility of hæmorrhoids or polypoid adenoma as the source of the latter must, of course, be remembered.

Treatment.—The teeth should be put into good order and any other source of infection should be removed. The food must be thoroughly masticated and should be of an unirritating character. The use of purgatives should be avoided, though liquid paraffin or a vegetable mucilage should be given if hard scybala are passed. In infective colitis a liquid culture of *B. acidophilus* should be taken, and an autogenous vaccine occasionally proves of value if

definitely pathogenic organisms, which are agglutinated by the patient's serum, have been isolated from the stools. Belladonna should be given before meals with the addition, if diarrhœa persists, of codeine.

Ulcerative Colitis

Ætiology.—Ulcerative colitis is a common disorder in England. Young adults are most frequently affected, and men and women with equal frequency.

Pathology.—Bacillary dysentery, the "bloody flux," has always been endemic in Great Britain, and it still occurs sporadically and in small groups in country districts and in larger epidemics in asylums and other institutions. The epidemic summer diarrhœa of infants is also generally due to infection with a dysenteric organism. The many cases of chronic ulcerative colitis give a history of an acute onset with "bloody flux," which may have lasted only a few days but recurred after intervals of varying length. In the only case in which to my knowledge the stools were examined at the acute onset Flexner's bacillus was isolated. It seems likely that the majority of cases are primarily the result of infection with a dysentery bacillus or some allied parenteric organism. The condition may become chronic owing to secondary infection with (1) the normal *B. coli* or enterococcus of the colon, which may develop toxic properties as a result of the excess of soluble protein and the blood and pus in the surrounding medium; (2) parenteric organisms, such as Gaertner's or Morgan's bacillus or *B. asiaticus*, swallowed at the same time as the original *B. dysenteriæ*, or subsequently; (3) streptococci from the throat as a result of an incidental attack of tonsillitis. The organism which caused the original infection often dies out just as it does in cases of chronic dysentery, which are clinically and pathologically indistinguishable from ulcerative colitis except for their known origin as acute bacillary dysentery. In 15 per cent. of my cases of ulcerative colitis and in many others of which I have knowledge, a dysentery bacillus was isolated from the stools, swabs from ulcers, or a scraping of the floor of an ulcer obtained with a sharp spoon. In a further 30 per cent. of my cases a parenteric organism has been isolated from the stools, and the patient's blood has agglutinated it.

Symptoms.—The onset is sometimes acute with severe diarrhœa and fever. More commonly it is subacute and insidious, the first symptom noticed being the passage of blood and mucus with or without diarrhœa. Even in cases which appear to begin acutely a history can often be obtained of slight intestinal irregularity with the occasional passage of mucus or blood for many months or even several years before the onset of severe symptoms.

Diarrhœa is always present; as many as twenty stools, most of which are quite small, may be passed in the day. Blood, pus and mucus are passed with semi-fluid fæces and also alone. In quiescent periods they may appear to be absent, but microscopical examination of the stools shows that this is not the case. Blood may be passed in large quantities by itself, but it is generally mixed more or less intimately with the mucus and pus. It is bright red, and never produces black tarry stools, such as are seen with gastric and duodenal ulcer. It is mostly fluid, but small clots are often present. The mucus is clear or opaque owing to the presence of pus; membranes are never passed. In most cases small collections of pus are easily recognised with the naked eye in addition to that mixed with the mucus and fluid fæces.

Abdominal discomfort is often, but not always, present. Actual pain is rare except immediately before defæcation, when colic may occur; this disappears as soon as the bowels are opened, especially if flatus is passed. Tenesmus is unusual and occurs only if the anal canal is involved. The abdomen is sometimes slightly distended, but in many cases it is retracted. Tenderness is often completely absent, even in severe cases, but pressure over the colon, especially in the left iliac fossa, may cause discomfort. If the tenderness is considerable, the inflammation has generally spread to the peritoneum and local peritonitis is present. A moderate degree of muscular rigidity is often found in severe cases, especially when there is any local peritonitis.

Digital examination of the rectum is painful only when the anal canal is inflamed. The thickened mucous membrane and the ulcers can be felt with the finger when the rectum is involved.

An examination should always be made with a long proctoscope; in the rare cases in which the rectum is healthy a sigmoidoscope must be used. An anæsthetic is never required, and if the instrument is carefully introduced under visual guidance without inflation and only as far as it goes without difficulty, there is no danger. The mucous membrane is bright red, thick and sometimes granular. It bleeds very readily when touched, and small submucous hæmorrhages are frequently seen. Its surface is covered with blood-stained, purulent mucus, some of which should be removed on a sterile swab for bacteriological and cytological examination. Superficial ulcers are invariably present; but in early cases they may be so small that they are difficult to recognise without a magnifying eye-piece if a sigmoidoscope and not a proctoscope is used. Later they are large, and are sometimes so extensive that only small islets of mucous membrane are left, which may feel like small, flat polypi on rectal examination, the floor of the confluent ulcers being mistaken for the surface of the mucous membrane. The ulcers are always superficial with irregular edges; the thick mucous membrane may be undermined. The floor of the ulcers appears greyish-yellow when the blood and mucus are wiped from their surface.

In acute cases, and in acute exacerbations of more chronic cases, irregular fever is generally present. Apart from this, the patient has generally a good appetite. The constant diarrhœa leads to progressive emaciation and weakness; but in mild cases the patient may feel so well that he is unwilling to undergo treatment in bed. The loss of blood leads to secondary anæmia, which may be severe; the hæmoglobin is often only 50 per cent. of normal, and may fall to 20 per cent. In such cases œdema of the ankles and ascites may develop.

Complications.—In the course of healing, strictures, which may be multiple and of considerable length, may develop, especially in cases of long standing. The symptoms do not alter with the development of the strictures, as the stools are so fluid that they pass without difficulty through the narrowed bowel. A narrowing can sometimes be recognised with the sigmoidoscope, but the exact degree and localisation can only be discovered with the aid of the X-rays. A stricture does not require surgery unless it causes stasis, which can be recognised with an opaque meal, but not with an enema. The X-rays also give some idea of the extent of colon involved, as the normal "haustration" produced by the constant activity of the muscularis mucosæ

disappears when it is paralysed by inflammation spreading from the mucous membrane to the submucous tissue. In the majority of early cases the distal half of the colon or the pelvic colon and rectum are alone affected.

Healing may also be associated with the development of multiple small polypi. The majority of the "polypi" are tags of inflamed mucous membrane, but true adenomatous polypi, which may later undergo malignant degeneration, also occur.

General peritonitis is a very rare complication, and is generally not due to perforation, but to direct spread of infection through the wall of the colon. Localised abscesses are still more unusual except in the perianal region, multiple fistulæ-in-ano being not uncommon; if undiscovered, they may give rise to recurrence after apparent recovery.

In rare cases non-suppurative multiple arthritis develops, as it does in bacillary dysentery.

In advanced cases with much anæmia and toxæmia the malnutrition and vitamin deficiency, which result from an unwisely restricted diet, may give rise to severe trophic lesions in the skin and eyes which recover rapidly when an adequate diet is given.

Diagnosis.—The association of blood in the stools with pus and mucus indicates the presence of ulcerative colitis or a growth of the pelvic colon or rectum. A growth can be excluded by rectal and abdominal palpation, and by the sigmoidoscope. Even if the growth is too high to be reached by the instrument, its presence is rendered very probable when the accessible part of the colon appears normal, and blood, mucus and pus are seen coming from the inaccessible part.

If the patient has been in the East the possibility of amœbic dysentery should be considered, though the absence of such a history does not exclude it, as I have seen several cases in people who have never been out of England. The endoscopic appearance is so distinct that a definite diagnosis can be made from this alone. Small, round, red elevations are seen on the otherwise normal-looking mucous membrane, corresponding with the collection of broken-down material in the submucous tissue caused by the invasion of *Entamœba histolytica*. In the centre of each elevation is a depressed yellowish ulcer, where the submucous abscess has broken through the mucous membrane.

I have seen a case of thrombocytopenic purpura with only a few cutaneous petechiæ, in which the passage of blood in the stools had led to a diagnosis of ulcerative colitis, but the sigmoidoscope revealed innumerable minute submucous hæmorrhages without any actual inflammation.

Prognosis.—Very acute ulcerative colitis may cause death in a few weeks. More commonly it becomes chronic with periodic acute exacerbations, and thus approximates to the ordinary form of ulcerative colitis, in which the onset is insidious and the course very prolonged. In private practice the mortality is about 10 per cent., but in hospital it is at least three times as great. Death is generally the result of exhaustion from prolonged diarrhœa, anæmia caused by constant bleeding and toxæmia.

Relapses tend to occur with acute infections, especially tonsillitis, food poisoning, dietetic indiscretions, exposure to cold and damp, worry, and fatigue from mental or physical overwork.

Treatment.—The most important factors in the successful treatment

of ulcerative colitis are patience and perseverance on the part of both doctor and patient. Even in early cases several weeks of strict treatment are generally required; in chronic and late cases the patient may have to be in bed under continuous supervision for a year or more. He should be kept at rest in bed so long as there is any pyrexia and so long as more than two or three stools are passed in 24 hours. After that he may be allowed to get up for a warm bath and to lie on a couch during the day, if possible in the open air, but he must take no more exercise than is involved in walking from one room to another until recovery is complete.

The small intestines are rarely involved in ulcerative colitis. It is, therefore, quite unnecessary to make any restriction in diet beyond the avoidance of pips and skins of fruit and fibres of vegetables. Too limited a diet results not only in loss of weight and strength, but the food may contain insufficient iron to compensate for the loss of blood in the stools so that microcytic anæmia develops. The anæmia and malnutrition, and particularly any deficiency in vitamins, aggravate the colitis and may lead to serious cutaneous and ocular complications, all of which respond rapidly to a change to a more liberal diet. Patients with ulcerative colitis often have quite a good appetite, and there is no reason for limiting their allowance of meat and other foods containing no indigestible residue. Fruit is best given in the form of strained juice and purées and green vegetables as purées.

Except in the most acute stages local treatment is often useful. The fluid should be run in through a soft catheter introduced only just beyond the anal sphincter. The quantity injected depends upon the extent of the disease as shown by X-ray examination. If the whole colon is involved a pint is needed; when introduced slowly at a pressure not exceeding 18 inches of water, it reaches the cæcum without difficulty and is almost as effective as if given through an appendicular stoma. If only the distal half is involved, half or three-quarters of a pint are sufficient, and the patient should remain in a semi-sitting position so that the fluid cannot run into the more proximal part of the colon. The most useful solution is tannic acid, the strength of which is gradually increased from half to two grains to the fluid ounce; it should be retained, if possible, for half an hour.

The most satisfactory method of giving local treatment in cases of hæmorrhagic proctitis, and of ulcerative colitis in which only the more distal parts of the colon are involved, is by injecting an emulsion of 5 grains of bismuth subgallate to the ounce of an unirritating vegetable mucilage made from isogel or coreine, which is neither affected by bacteria nor absorbed. The emulsion can generally be retained for several hours and should be given directly after the bowels have opened in the morning or at night. For proctitis 4 fluid ounces are required; when the pelvic colon is involved 6 or 8 fluid ounces should be injected. Some patients are able to retain 10 or 12 fluid ounces; this quantity is often sufficient to spread through the whole colon, so that the treatment can be tried as a substitute for injections of tannic acid solution in all cases of ulcerative colitis. Occasionally water is absorbed and difficulty is experienced in evacuating the emulsion in the morning; in such cases one or two fluid ounces of paraffin should be incorporated in the emulsion.

When the diarrhœa is severe the patient is likely to become exhausted by want of sleep. A dose of codeine sufficient to keep the bowels from acting

more than once in the night should be given at 10 p.m. and a smaller dose may be given before meals and immediately before the injection of a retention enema. In most cases the muscular coat of the colon is extremely irritable, and healing is retarded by its continuous activity. Tincture of belladonna should therefore be given every 4 hours, the dose being gradually increased from 5 minims to the maximum the patient can take without getting his mouth uncomfortably dry.

Pain is not a common complaint in ulcerative colitis. Colicky pains may, however, occur owing to distension with gas, especially shortly before the bowels act. They can always be relieved by giving a tablespoonful of activated charcoal two or three times a day.

Most patients with ulcerative colitis are more or less anæmic; 30 grains of iron and ammonium citrate should be given three times a day till the hæmoglobin is at least 80 per cent. If the hæmoglobin percentage is less than 70, repeated small transfusions not only improve the patient's general condition, but often greatly hasten the healing of the ulcers.

The injection of polyvalent anti-dysenteric serum is occasionally followed by dramatic improvement, but in many cases little or no benefit follows. After preliminary desensitisation 20, 40, 60, 80 and 100 c.c. are injected intravenously on consecutive days. Alternatively 10 c.c. of serum can be injected intramuscularly daily for about 10 days; good results are sometimes obtained, though less frequently than with intravenous injections. The great disadvantage of treatment with serum is the possibility of dangerous anaphylactic reaction, which may occur during the injection but is occasionally delayed several hours. Prompt treatment with solution of adrenaline, 1 minim of which should be injected every half minute after an initial injection of 3 minims until complete recovery takes place, is almost always effective. Though the improvement which follows serum treatment is probably in part due to protein shock, especially in cases in which there is much general reaction, yet in some cases it appears to be specific.

I have never seen the slightest benefit follow any form of vaccination, and in some cases the local condition has been definitely aggravated. Several American physicians have told me that they have been quite unable to confirm Bargen's enthusiastic reports about treatment with the vaccine and serum (so-called "ulcerative colitis serum") produced from his diplostreptococcus, which is regarded by most bacteriologists as a non-pathogenic variant of the normal enterococcus of the colon.

The danger of recurrence is much reduced if treatment is continued until endoscopy shows no trace of inflammation, even if symptoms have already disappeared for some weeks. Associated conditions, such as oral and pharyngeal infections and anal complications, must be treated, as a relapse may follow an acute sore throat or the development of a peri-anal abscess or a fistula-in-ano. The patient should keep permanently on a roughage-free diet and, when necessary, take sufficient paraffin to keep his stools soft.

As the whole of the colon can be satisfactorily washed out with 1½ pints of fluid introduced per anum, and as in many cases only the distal half is involved, appendicostomy and cæcostomy are never indicated. There are three indications for ileostomy. (1) It gives the only chance of recovery in the very rare acute fulminating cases with high temperature and passage of

large quantities of pus and blood. The divided ileum can be rejoined some weeks later. (2) When continuous treatment under good conditions for nine months has led to no improvement, and (3) when fibrous strictures or polypi have developed, the terminal ileum should be divided and both ends brought to the surface. The ileostomy causes very little trouble and the patient is soon able to lead a life of normal activity. When there is no longer any anal discharge and washings through the colon contains no pus cells or red corpuscles, diluted fæces from the ileostomy should be injected into the colon in increasing strength. If there is no reaction, it is generally safe to rejoin the ileum unless strictures or polypi are present, in which case the colon should be excised up to about 9 inches from the anus. Some months later the ileum can be joined to the cut end of the pelvic colon after any polypi present have been destroyed and strictures dilated per anum.

TUBERCULOUS ENTERITIS AND COLITIS

Ætiology.—Miliary tubercles may be present in the intestines in general tuberculosis, but they have no clinical importance. Primary infection of the bowels from tuberculous milk is not infrequent in children, but is comparatively rare in adults. Secondary infection from swallowing tuberculous sputum is very common, ulceration being present in 50 per cent. of fatal cases of pulmonary tuberculosis. The lower end of the ileum and the cæcum, where the rapid passage of chyme along the alimentary tract is first arrested so that there is time for the muco-pus in which the tubercle bacilli of the sputum are enmeshed to be digested, are the parts most frequently affected.

Symptoms.—In many cases no symptoms are present, although extensive ulceration may be found *post mortem*. Tuberculous enteritis should be suspected in children suffering from diarrhœa with fever, abdominal distension, enlarged glands, anæmia, wasting and weakness. It should also be suspected when pulmonary tuberculosis is associated with diarrhœa, especially if abdominal pain and tenderness are present and blood is found in the stools. Tubercle bacilli are often present as a result of swallowing infected sputum even with healthy intestines. In the absence of abdominal pain the diarrhœa in advanced phthisis is sometimes due to the achlorhydria which is commonly present.

Perforation of a tuberculous ulcer is rare owing to the adhesions which form between the coils of intestine. Cicatrisation of ulcers may lead to single or multiple strictures of the small intestines; as these are incomplete and the contents of the bowel are fluid, obstruction is rarely produced. External adhesions and the formation of bands may, however, lead to acute intestinal obstruction.

Tuberculous ulceration of the last few inches of the ileum may produce reflex dyspepsia. In such cases when the terminal ileum is visualised with the X-rays it is found to be tender; its lumen may be irregular and thickening may be recognised on palpation. The X-rays may show a group of opaque glands in the ileo-cæcal angle. The stools generally contain occult blood, and there is often mild intermittent pyrexia. At a later stage small intestine peristalsis may become visible, and palpable stiffening of a coil of ileum, which disappears with a gurgle, sometimes occurs, although the bowels may

remain regular until acute obstruction supervenes. In a case under my care multiple strictures of the colon were recognised with the X-rays; recovery followed partial colectomy, and the strictures were found to be caused by cicatrisation of tuberculous ulcers.

What has been described in the past as *hyperplastic tuberculosis of the cæcum* is probably a form of regional ileitis (p. 647) in which the cæcum is involved as well as the end of the ileum. It was always recognised that the condition was not associated with tuberculous foci elsewhere and tubercle bacilli were never found in the stools; there was in fact no evidence that the condition was tuberculous in origin.

Treatment.—The treatment is that of tuberculosis in general, combined with the dietetic restrictions required for non-tuberculous entero-colitis.

POLYPI OF THE COLON: POLYPOSIS

Ætiology and Pathology.—Solitary polypi of the colon are common, and cases with two to twelve are not infrequent. True polyposis, in which the whole or part of the colon is studded with innumerable polypoid adenomata, is very rare.

The polypi generally begin as small flat patches of mucosal overgrowth which soon become polypoid. Exactly similar polypi may develop in the process of recovery from ulcerative colitis; they are generally present in small numbers, but occasionally a condition of generalised polyposis develops which is indistinguishable from the primary condition.

Most cases of primary generalised polyposis are familial, several members of one or more generations of a family being affected. Less frequently single polypi are also familial.

Males are more often affected than females, and the symptoms generally begin before the age of 30.

Symptoms.—Recurrent passage of bright red blood, unmixed with mucus or pus, sometimes with and sometimes independent of fæces, is generally the first and often the only symptom. In adults internal hæmorrhoids give rise to similar symptoms, but in children polypi are the only common cause. In polyposis diarrhœa always develops sooner or later as a result of secondary infection and inflammation, and the fluid fæces are mixed with mucus, pus and bright blood, being indistinguishable from those passed in ulcerative colitis. The hæmorrhage may lead to severe anæmia, and the diarrhœa to malnutrition and, when it begins in childhood, to infantilism. Tenesmus and abdominal pain are uncommon.

The polypi can often be felt on rectal examination and can generally be seen with a proctoscope or sigmoidoscope, but occasionally they are situated too far from the anus, when the X-rays are the only means of making a definite diagnosis. Their exact extent can be estimated by means of an opaque enema which gives a characteristic picture, showing rounded semi-translucent areas in the shadow of the colon. Sometimes they are best demonstrated by inflation of the colon with air after the greater part of the opaque enema has been evacuated.

Polypi are the most common exciting cause of chronic intussusception.

Both single and multiple polypi show a considerable tendency to become

malignant, and the majority of patients with familial polyposis ultimately die of carcinoma. In most cases of carcinoma of the rectum and colon the lesion is probably grafted on a simple polypous adenoma. Thus in 75 per cent. of 33 specimens of carcinoma of the rectum and pelvic colon removed at operation simple adenomata were also present (Dukes), and in nearly all very early cases of carcimona the adenomatous origin can be recognised. Malignant degeneration may occur in more than one polyp either at the same time or after an interval.

Treatment.—Single and multiple polypi in the rectum and pelvic colon can be removed with a diathermy snare or destroyed by a diathermy cautery through a proctoscope or sigmoidoscope. The patient should be re-examined every 4 months for at least 10 years, so that any new polypi which develop can be destroyed before they have time to undergo malignant degeneration. Multiple small polypi sometimes disappear when treated with deep X-rays. When the whole colon is involved, the terminal ileum should be anastomosed with the lower end of the pelvic colon, the rest of the colon being excised. The polypi present in the remaining part of the pelvic colon and in the rectum are removed or destroyed by diathermy.

CANCER OF THE COLON

Ætiology.—Primary columnar-celled carcinoma of the colon attacks men with slightly greater frequency than women. It is most common between the ages of 40 and 65, although cases have been recorded in early childhood.

Pathology.—Only a little over 1 per cent. of cases of intestinal cancer affect the small intestine. Of the remainder 50 per cent. are in the rectum and at the pelvi-rectal flexure, and 25 per cent. in the iliac and pelvic colon; thus 75 per cent. of cases occur in parts of the colon where the fæces are solid. Nearly half of the remainder are in the cæcum and ascending colon.

The adenomatous origin of colonic carcinoma is discussed in the previous section.

Extension to the peritoneum and secondary deposits in the lymphatic glands, liver and other organs develop later and rather less frequently with cancer of the intestine than with cancer in most other situations, obstruction occurring in more than 50 per cent. of cases before the glands are involved. The prospect of a radical cure by operation, if an early diagnosis is made, is therefore comparatively good. The rectum has a moderate supply of lymphatics and gives operative results intermediate between gastric and colonic carcinoma.

Symptoms.—The possibility of cancer of the intestine should be considered whenever an individual over the age of 35, whose bowels have previously been regular develops, without change of diet or habits, constipation or diarrhœa, or when a patient of the same age, who is habitually constipated, becomes more so without obvious reason. Constipation occurs earliest in the common annular form of intestinal cancer, which narrows the circumference of the bowel while the actual size of the growth is still very small. Less obstruction is caused by papillomatous carcinoma, which forms

a friable and ulcerated mass, projecting into, but not obliterating, the intestinal lumen; constipation is at first intermittent and relieved by purgatives, which gradually become less effective and cause more pain. Enemata are generally of use for a longer period, but they also finally fail to act. Sometimes, however, there is persistent diarrhœa from the start, especially when the growth is situated in the pelvic colon. More frequently the initial constipation is interrupted by attacks of diarrhœa. In the majority of cases the constipation becomes steadily more severe until it ends in complete obstruction, which is sometimes hastened by the impaction of a hard mass of fæces in the narrowed lumen.

The stools do not generally differ in shape from those seen in ordinary constipation. Occasionally thin pieces, resembling the fæces formed in some cases of constipation associated with spasm, are passed, especially when the growth is in the pelvic colon or in the rectum; they sometimes owe their shape to spasm of the anal sphincter, produced reflexly by the growth or by the irritating discharge from its surface, but I have also seen ribbon-shaped fæces appear through a stricture six inches from the anus during a sigmoidoscopic examination. The stools in cancer of the rectum and lower part of the pelvic colon generally contain obvious blood, pus and mucus. In rare cases the passage of a large quantity of bright red blood is the first symptom. The stools may closely resemble those of simple ulcerative colitis, but fæcal matter is often absent and fragments of more or less solid fæces can sometimes be recognised, whereas in ulcerative colitis unformed fæces are almost always present. When the growth is proximal to the middle of the pelvic colon, blood and pus can rarely be recognised with the naked eye, but occult blood can always be found by the guaiac test. The spectroscope often shows that acid hæmatin as well as hæmatoporphyrin is present in contrast with the occult blood of gastric and duodenal origin, which gives the latter spectrum alone unless the quantity present is unusually great.

Vague discomfort in the lower part of the abdomen is often present, sometimes without any irregularity of the bowels, and slight attacks of colic occur when constipation becomes severe, but they rarely reach any great intensity until the obstruction is almost complete. In some cases, especially in cancer of the cæcum, hepatic flexure and splenic flexure, the pain may travel in a definite direction to a certain point, where the patient occasionally feels a rumbling sensation; this generally corresponds with the situation of the growth. When the pelvic colon is involved, the pain is always below the umbilicus and is often most marked on the left side.

The over-activity of the colon above the obstruction leads to hypertrophy of its musculature. When the obstruction becomes complete, failure of the muscle ultimately occurs and extreme paralytic distension results; ulceration and perforation, especially of the cæcum, may follow.

When the obstruction is sufficient to give rise to severe colic, strong spasmodic contractions of the colon, but not peristaltic waves, are often visible and palpable. They never occur in the colic associated with lead poisoning or colitis, and very rarely with obstruction due to simple impaction of fæces.

In cancer of the cæcum and ascending colon general symptoms, especially anæmia, are often present for a considerable time before any change takes

place in the activity of the bowels. Severe anæmia may indeed develop in the absence of any symptoms pointing to an abdominal disorder.

In about 30 per cent. of cases when the patient is first seen, a tumour is palpable either on abdominal or rectal examination. In some of the remainder the growth is inaccessible to palpation owing to its situation at the splenic flexure; in others the tumour is too small to be palpable. It is often impossible to reach a growth in the lower end of the pelvic colon or at the top of the rectum either by abdominal or rectal examination, though it may be accessible to bimanual palpation. In such cases the sigmoidoscope alone makes an early diagnosis possible. If acute obstruction is not an early occurrence, the growth develops into a large and easily palpable tumour, which invades the neighbouring peritoneum and viscera. The tumour often varies in size from time to time, as it is formed not only by the growth itself, but partly by impacted fæces or by thickened peritoneum and adherent coils of intestine, with perhaps a localised abscess. The disappearance of a tumour after treatment with purgatives or enemata does not therefore mean that cancer is absent, even if its disappearance is associated with improvement in the symptoms. For a mass of fæces can become impacted above a cancerous stricture and produce obstruction, which may be partially relieved when the fæces are removed. A diagnosis of cancer can only be excluded when the disappearance of the tumour is accompanied by complete and lasting cure of all the symptoms. The tumour produced by a growth is hard; it is rarely very tender, unless complicated by local peritonitis. When situated in the ascending, descending or iliac colon it is generally fixed; in the cæcum and transverse colon it is frequently very movable.

The X-rays often afford considerable help in diagnosis. The shadow of the colon may be visible as far as the seat of obstruction unusually soon after the opaque meal; little or no barium may pass beyond this point for a considerable time, but this may also occur in simple constipation. The passage of an opaque enema is often obstructed at a period in the disease when an opaque meal is not delayed. In most cases, especially when an enema is used, a filling defect caused by the tumour can be observed. When a tumour is present, the combination of abdominal palpation and X-ray examination shows whether any delay in the passage of fæces occurs in the neighbourhood of the tumour and whether the latter arises from some part of the alimentary canal. The X-rays may completely fail to give any evidence of a growth until some months have elapsed since the onset of symptoms, but with modern technique this should happen very rarely.

In exceptional cases symptoms are produced by complications before the intestinal functions become affected. Thus secondary deposits in the brain may cause cerebral symptoms sufficient to overshadow everything else, and an abscess developing in connection with an ulcerated growth or a stercoral ulcer above the obstruction, or general peritonitis resulting from perforation of the ulcer may constitute the earliest clinical manifestation. I have seen two cases in which no symptoms occurred until the development of a gastro-colic fistula.

Diagnosis.—The diagnosis depends upon the history combined with the results of abdominal and rectal palpation, examination of the stools for visible or occult blood, sigmoidoscopy and the X-rays. A tumour in the right iliac fossa may be caused by an inflammatory mass developing round a

small chronic appendicular abscess, by regional ileitis and by actinomycosis of the cæcum as well as by cancer. In the left iliac fossa confusion with diverticulitis is likely to occur. In the latter occult blood is often absent, and the diagnosis can generally be settled by means of the X-rays. The chronic obstruction caused by a local band of adhesions may simulate that caused by a growth, the difficulty being increased by the fact that the stools may contain occult blood.

Prognosis.—Improved methods of examination have made it possible to diagnose the large majority of cases of cancer of the colon as soon as symptoms appear and before any serious degree of obstruction has developed. As glandular involvement and secondary deposits in the liver and other organs occur comparatively late, in most such cases the growth can be completely removed, and many of my patients are still in perfect health several years after the operation. If operation be delayed until acute obstruction is present, the immediate prognosis is very bad, but in subacute obstruction a two-stage operation is often successful.

Treatment.—Cancer of any part of the large intestine proximal to the middle of the transverse colon is best treated by the removal of all the colon up to three inches beyond the growth, an ileo-colostomy being simultaneously performed. Beyond this point resection of the growth and of a sufficient margin on each side with end-to-end anastomosis is more satisfactory. If the slightest obstruction is present, the operation should be performed in two stages, excision being only performed after the patient recovers from a preliminary colostomy.

DIVERTICULOSIS: DIVERTICULITIS

Ætiology and Pathology.—Diverticulosis, the presence of diverticula in the colon, occurs in about 5 per cent. of men and women over the age of 40. They are especially likely to occur if aperients have been habitually used for many years. Owing to the atrophy of the muscular coat of the colon which occurs in old age, pressure from within produces diverticula more readily than in earlier life. The presence of fat diminishes the resistance of the intestinal wall, so that diverticula are especially likely to occur in the obese and they often form in the appendices epiploicæ.

The diverticula increase in number and size as the lower end of the pelvic colon is approached, but they are very rare in the rectum owing to the thickness of its muscular coat. A large number are generally present; some are so small that they are barely visible to the naked eye, whilst others attain a diameter of half an inch. They very rarely become larger than this, as secondary pathological changes interrupt their growth. In the walls of the smaller diverticula all the coats of the bowel are represented. As they grow larger the muscular layer gradually disappears and the mucous membrane frequently becomes atrophied.

Symptoms.—*Diverticulosis*, the simple presence of diverticula of the colon, is a very common condition and gives rise to no symptoms. Inflammation of diverticula, *diverticulitis*, occurs in about 15 per cent. of cases. Most frequently the patient complains of discomfort in the lower part of the abdomen and, after a time, attacks of colic, which gradually increase in

severity and in frequency. The discomfort is generally most marked in the left iliac fossa. At the same time the constipation, for which the patient has taken aperients for many years, may become more severe. Aperients aggravate the pain, which is relieved to some extent by the passage of flatus or fæces. Mucus may be present in the stools, and pus cells can occasionally be discovered on microscopical examination, but obvious and occult blood is generally absent.

The temperature is sometimes slightly raised, and in acute exacerbations it may be very high and accompanied by severe constitutional symptoms with polymorphonuclear leucocytosis.

The bladder is often irritable, the patient having to pass urine with abnormal frequency. At a later stage adhesions with the bladder may develop and lead to cystitis, and in rare cases gas and fæces are finally passed *per urethram* owing to the development of a vesico-colic fistula, diverticulitis and not cancer of the colon being the cause of the majority of cases of this condition.

Diverticulitis, like appendicitis, may cause reflex gastric dyspepsia.

Tenderness is most marked in the left iliac fossa and occasionally immediately above the pubes. The rigidity of the abdominal wall over the tender area may make palpation difficult, but in most cases it is possible to feel the irregularly thickened and extremely tender iliac colon. Digital examination of the rectum generally reveals nothing abnormal, but I have felt a mass suggestive of a secondary malignant deposit in Douglas's pouch which was caused by thickening round inflamed diverticula of the pelvic colon. The sigmoidoscope often cannot be passed farther than the pelvi-rectal flexure or an inch or two beyond, the bowel at this point appearing to be abnormally fixed and its lumen narrowed. I have never been able to see the mouths of diverticula at the lower end of the affected portion of the pelvic colon.

An opaque meal shows that there is generally little or no delay in the passage through the bowel till the iliac colon is reached. The presence of diverticula can often be recognised when the barium reaches the affected part, as some of it enters and remains in them after the rest has been evacuated. A barium enema should also be given, as whenever diverticula are present their number and localisation can be more accurately determined in this way than by any other method. They may be discovered directly the enema is given, but more often only after it has been evacuated, a double row of small rounded shadows representing the diverticula being then seen, especially in the position of the iliac and pelvic colon. They often remain visible for several days.

Diagnosis.—Discomfort and colicky pain in the lower part of the abdomen in middle-aged and elderly patients, especially if associated with increasing constipation, should raise the suspicion of diverticulitis or a growth of the colon. If the pain is most marked in the left iliac fossa and if it is associated with bladder irritability, the former is the more probable diagnosis. A tender tumour in the left iliac fossa, associated with muscular rigidity is much more frequently due to diverticulitis than to cancer. An X-ray examination after an opaque meal and an opaque enema generally settle the diagnosis. Diverticulitis is not a pre-cancerous condition, as the occasional association with cancer is no more frequent than can be explained by coin-

cidence, and the incidence of cancer in simple diverticulosis is as great as in diverticulitis. When cancer is present the stools contain pus and blood, whereas even occult blood is usually absent in uncomplicated diverticulitis, and an opaque enema reveals a filling defect in addition to the diverticula, which do not necessarily involve the same part of the colon.

Treatment.—The accidental discovery of diverticulosis in the course of a routine X-ray examination indicates the necessity for keeping the stools permanently soft by means of paraffin or an unirritating vegetable mucilage, and the avoidance of pips and skins of fruit, pickles and salads, and cooked green vegetables except as purées. No aperients should be used, as they tend to force the fluid fæces into the diverticula. In very mild diverticulitis the same treatment is effective. In more severe cases with pyrexia and abdominal rigidity the patient should be kept in bed till all signs of active inflammation have disappeared. The diet already mentioned should be given together with an ounce of paraffin three times a day. Belladonna in frequent and maximal doses may be required to control the secondary spasm. Six fluid ounces of paraffin should be injected into the rectum every evening and retained during the night. If the bowels do not act satisfactorily in the morning, water should be run into the rectum slowly and under low pressure in quantity insufficient to cause pain. By this means the accumulation of fæces generally present is gradually evacuated, and the pain and inflammation subside.

Very few cases require operation. Large inflammatory masses associated with a high temperature and leucocytosis often completely disappear with medical treatment, and a considerable degree of obstruction may be overcome. I have seen only one case requiring operation in the last fifteen years. Only if the symptoms become worse in spite of treatment, or if the condition is complicated by the development of an abscess, signs of spreading peritonitis, or intractable cystitis suggesting that a vesico-colic fistula is about to form, is an operation indicated. It is sometimes possible to excise or short-circuit the whole of the affected portion of the bowel, but more often a colostomy has to be performed.

CHRONIC INTUSSUSCEPTION

Ætiology.—Chronic intussusception is a rare disease occurring only in adults. Twenty per cent. are secondary to innocent and 15 per cent. to malignant tumours, most of which project as polypi into the lumen of the bowel. A case of mine was associated with chronic uræmia in a man suffering from nephritis due to lead poisoning.

For Acute Intussusception *vide* Acute Intestinal Obstruction, p. 671.

Symptoms.—A chronic intussusception may last for a month, a year or longer before it terminates in an attack of acute obstruction or of general peritonitis from perforation. It may finally reach the anus, from which it may project for some inches without preventing the passage of fæces. The onset is generally insidious; occasionally it is acute, but the severity of the symptoms generally diminishes and the subsequent progress of the case is chronic. Only about half of the cases are accompanied by constipation, diarrhœa being present in the majority of the others. The most prominent

symptom is colic, occurring in attacks which steadily increase in frequency and severity, and which may be brought on by taking food or by aperients; constipation is present during the attack, and blood and mucus may be passed at frequent intervals in entero-colic and colic, but not in enteric, intussusceptions. A palpable tumour is present in half the cases; it becomes harder and longer during an attack of colic, and appears to recede in the intervals. Severe attacks are accompanied by vomiting, especially in the enteric form. Visible peristalsis and dilatation may occur in the intestines above the intussusception. An opaque enema, given for suspected chronic obstruction, may reveal the presence of an intussusception by the typical appearance produced when a small quantity of fluid penetrates between the intussusceptum and the intussuscipiens.

Treatment.—The treatment is always surgical.

ANAL ACHALASIA AND MEGACOLON (HIRSCHSPRUNG'S DISEASE)

Definition.—Megacolon is a condition in which the rectum and pelvic colon and sometimes the whole of the large intestine are dilated and hypertrophied, although no organic obstruction is present.

The name Hirschsprung's disease, which is generally used to describe megacolon in children, should be discarded, as von Ammon gave a good description of two cases in 1842, forty-four years before Hirschsprung, and no clear dividing line can be drawn between the megacolon of children and that of adults, to which the name of Hirschsprung's disease is never applied.

Megacolon must be distinguished from a colon of abnormal length—*dolichocolon*. The pelvic colon varies greatly in length, but although a very long pelvic colon may predispose to volvulus, there is no reason to believe that it predisposes to megacolon.

Ætiology and Pathogenesis.—Megacolon in children is rare; I have seen only 10 cases compared with 36 in adults. Whereas in children it occurs almost exclusively in boys (9 out of 10 of my cases), the incidence is about equal in the two sexes in adults: there were 19 males and 17 females in my series. It is probable that the majority of cases observed in adult life do not date from childhood, as otherwise it would not occur so often in women, and the history of the onset of symptoms, though generally very vague, supports this view. There is, however, no doubt that many children with "Hirschsprung's disease" attain adult life, although the megacolon remains.

I believe that the primary factor in the pathogenesis of almost all cases of megacolon is achalasia of the sphincter ani—absence of the relaxation of the sphincter, which normally occurs when the rectum contracts during defæcation. Simple absence of normal relaxation without any added spasm of the sphincter is sufficient to prevent the easy evacuation of fæces, which are consequently retained. Under normal conditions gas can escape from the rectum by voluntary relaxation of the sphincter at any time; when achalasia is present voluntary relaxation is no longer possible, so gas as well as fæces accumulates in the rectum and pelvic colon.

The pelvic colon and rectum attempt to overcome the resistance offered by the closed anal sphincter by increased peristalsis with the result that their walls gradually become hypertrophied. This is at first sufficient to prevent any serious accumulation of fæces and gas, but after a time the amount of retention gradually increases. The thick walls of the fixed rectum give way less readily than the comparatively thin walls of the freely movable pelvic colon, so that the rectum does not show the same degree of dilatation as the pelvic colon, and in many cases it is only slightly enlarged. The distension of the pelvic colon results in an increase in its length as well as its diameter; as it contains a great excess of gas the dilated and elongated loop rises during the day when the individual is in the erect position, and eventually its upper extremity generally reaches the left dome of the diaphragm.

In adults the extreme degree of hypertrophy and dilatation does not as a rule extend beyond the pelvic colon, though some slight dilatation and hypertrophy are often present in parts or all of the rest of the colon. The same was true in most of the cases I have seen in children, but in only a third of the neglected cases which come to post-mortem is the extreme dilatation confined to the pelvic colon and rectum.

Megacolon is the result of disturbance in the normal balance between the sympathetic and parasympathetic nerve supply to the sphincter. This might theoretically be due to overactivity of the sympathetic, stimulation of which inhibits the movements of the pelvic colon and rectum and causes spasm of the sphincter ani, or to under activity of the parasympathetic, stimulation of which causes contraction of the pelvic colon and rectum and relaxation of the sphincter. The great hypertrophy of the muscular coat of the pelvic colon is clearly the result of overactivity and not of inhibition, which would tend to produce atrophy. Moreover, in the large majority of cases the examining finger meets with normal resistance on rectal examination, spasm being present only in exceptional cases. Long-continued spasm would lead to hypertrophy of the sphincter, but no hypertrophy can be recognised on palpation, and *post mortem* the absence of hypertrophy of the sphincter is in striking contrast with the hypertrophy of the wall of the pelvic colon and rectum. In all probability, therefore, the disturbed innervation which gives rise to megacolon takes the form of underactivity of the parasympathetic. In most cases the parasympathetic deficiency is confined to the fibres supplying the anal sphincter with the production of achalasia; the changes in the pelvic colon and rectum are a result of the obstruction offered by the closed sphincter. The parasympathetic deficiency is the result of inflammation, simple degeneration, or fibrosis of the myenteric (Auerbach's) plexus, which have been found in several cases of megacolon both in children and adults.

If, at the onset of dilatation of the pelvic colon, the fold of mucous membrane at the pelvi-rectal flexure is unusually prominent, the dilatation of the part immediately proximal to it may exaggerate the kink and prevent the passage of fæces and gas into the rectum. Although the primary condition is still the anal achalasia, the secondary obstruction caused by the kink at the pelvi-rectal flexure prevents the rectum from becoming distended with gas and fæces. In spite of this it always appears much enlarged when an opaque enema is given, showing that it must have been greatly distended at first, but that when the pelvi-rectal kink developed and gas and fæces

ceased to accumulate in the rectum, it contracted down without, however, losing the abnormal distensibility caused by the earlier distension.

In the majority of cases the sigmoidoscope can be passed its full length of 12 inches blindly without meeting any resistance, whereas in normal individuals it is very rarely possible to pass it beyond the pelvi-rectal flexure without having to withdraw the obturator and guide the instrument with the aid of direct vision. Endoscopy shows the end of the instrument in the centre of an enormous cavity. On withdrawing it no dividing-line can be recognised between the pelvic colon and rectum, the dilatation of which extends to the entrance of the anal canal. In some cases the rectum is only slightly dilated or is normal in size, and occasionally its walls have collapsed to obliterate the lumen. It is then difficult to pass the sigmoidoscope round the pelvi-rectal flexure into the pelvic colon. If, however, the window of the instrument is removed, the patient being in the knee-elbow position, air enters and the rectum dilates. No difficulty is now experienced in passing the sigmoidoscope into the pelvic colon. Nothing suggesting the presence of a pelvi-rectal sphincter, closed as a result of either achalasia or spasm, is ever observed.[1]

In well-compensated cases and in patients under treatment the rectum is either empty or contains a small quantity of fæces. Small, soft scybala or unformed collections of soft fæces are often seen sticking to the mucous membrane at different points in the enormously dilated pelvic colon. Presumably they are propelled along the mucous membrane by the activity of the hypertrophied muscularis mucosæ.

Megacolon, secondary to spasm of the anal sphincter, is in rare cases associated with spasm of the sphincter of the bladder with dilatation and hypertrophy of the bladder and ureters. The lesion in such cases must be situated either in the central nervous system or in the large sympathetic plexuses, from which fibres pass to both the rectal and bladder sphincters.

Symptoms.—In children with megacolon there is almost always a history of constipation dating from birth or from the first few months of life. At an early stage the bowels cease to act spontaneously, and drugs gradually lose their effect until an evacuation can be procured only by means of enemata. The stools are generally soft, but in early cases hard scybala may be passed. Soon after the onset of constipation the abdomen, which is normal in appearance at birth, begins to increase in size owing to distension of the colon with gas and fæces, the size varying from time to time according to the extent to which the bowels are opened. Enormously dilated segments of colon can often be recognised through the stretched abdominal wall; they are dull on percussion, and palpation shows that they are filled with soft unformed fæces. The rectum is generally much dilated and filled with soft fæces or less frequently with a large solid fæcal ball. If secondary obstruction has developed at the pelvi-rectal flexure, the rectum is empty and fæces can be felt in the pelvic colon through its anterior wall. With proper treatment the child can lead an ordinary life and has no symptoms of toxæmia.

[1] In most discussions on the pathogenesis of megacolon it is assumed that a sphincter exists at the pelvi-rectal flexure. Sigmoidoscopy and radiology in normal individuals show, however, that there is never any uniform constriction at the pelvi-rectal flexure such as would be produced by a sphincter, the lumen of the pelvic colon being separated from that of the rectum by the uppermost Houston's fold and by nothing else.

If neglected, enormous accumulations of fæces collect, and formerly, before the true nature of the condition was recognised, the bowels sometimes ceased to act at all and death occurred from chronic fæcal obstruction.

Megacolon in adults may give rise to no symptoms beyond a mild degree of constipation. The abdomen is often not obviously distended.

The gas in the dilated pelvic colon is under considerable pressure. In small children it pushes the diaphragm up and the abdominal wall forward, but in older children and in adults the appearance of the abdomen is generally less abnormal and is sometimes quite normal, as the diaphragm, which receives no support from above owing to the negative intra-thoracic pressure, gives way earlier than the abdominal muscles. The increase in the capacity of the upper part of the abdominal cavity produced in this way provides sufficient space for the greater part of the dilated colon. In spite of the fact that the diaphragm is almost completely out of action and that the capacity of the chest is much reduced, there is no complaint of dyspnœa. Several of my patients were able to take strenuous exercise without difficulty, and the majority were physically well developed. In most cases the left dome of the diaphragm is alone involved; it may reach the level of the third or fourth rib and is always higher than the right dome. In 2 of my cases the heart was pushed over to the right. In 5 the pelvic colon was so long and dilated that its upper extremity crossed the middle line after reaching the diaphragm on the left side and passed upwards in front of the liver so as to intervene between its upper surface and the right dome of the diaphragm. Its gas-containing cavity was seen with the X-rays to be in contact with the diaphragm on both sides.

Eventration of the Diaphragm.—As the diaphragm in megacolon is displaced into what is normally part of the thoracic cavity, the condition present might with justice be called eventration of the diaphragm. This name is, however, generally reserved for a condition in which the high position of the diaphragm is the result of a congenital defect in the musculature of the left half of the diaphragm, which is represented by a fibrous membrane containing only a few scattered muscle fibres. In deep respiration it moves passively up in inspiration and down in expiration—*i.e.* in the reverse direction to that taken by the normal right half of the diaphragm. When the high position of the diaphragm is secondary to megacolon there is a small movement in the normal direction.

The eventration of the diaphragm which results from maldevelopment of its musculature is very rare compared with that due to megacolon, as I have seen only 2 cases of the former compared with 42 of the latter.

If the term "eventration of the diaphragm" is to be retained at all, it would be more logical to include all cases in which the diaphragm is abnormally high, instead of confining it to those in which it results from a congenital defect in development. Cases would then be classified as follows:

(1) Primary and due to maldevelopment of one-half of the diaphragm. This is always left-sided.

(2) Secondary to atrophy following interference with the nerve supply. This may, of course, occur on either side. It is a result of (*a*) disease, most commonly secondary carcinoma, but occasionally primary carcinoma of the lung, tuberculosis, Hodgkin's disease and aneurysm; and (*b*) therapeutic division or avulsion of the nerve.

(3) Secondary to (*a*) aërogastrie bloquée (p. 575) and (*b*) aërocolie bloquée in megacolon.

Radiological Examination.—Every X-ray examination should begin with an inspection of the patient in the erect position before he has had an opaque meal or enema. The possibility of a megacolon is at once suggested by the discovery of eventration of the diaphragm. The abnormally high position of the left dome of the diaphragm presents such a striking appearance that it can hardly be missed. I have already pointed out that it is much more frequently caused by megacolon than by primary atrophy of the diaphragm, in which the left side moves upwards during inspiration while the right side moves downwards in the normal manner. It is generally possible in megacolon to recognise the outline of the enormously dilated air-containing loop of pelvic colon and to distinguish it from an abnormally large gas-bubble in the fundus of the stomach, which is always limited below by the horizontal upper border of the shadow of the gastric contents. When a gas-containing cavity is seen under the right dome of the diaphragm, as well as the left, the diagnosis of megacolon is certain.

An opaque meal does not help greatly in the diagnosis of megacolon, but it is a very valuable corrective for the false conclusions which are likely to be drawn from an examination after an opaque enema. It shows how much of the colon is undilated, the degree of stasis present and where the stasis occurs. The small intestine is always normal, and in most cases the large intestine as far as the end of the iliac colon is normal in size and shows little or no stasis. When the barium passes beyond the iliac colon it is lost in the large cavity of the pelvic colon, small spots of opaque material being scattered over the whole of the enormous area it occupies. Stasis of varying degree is always present in the pelvic colon. In well compensated cases, in which the bowels are opened daily, there is no delay in the evacuation of the greater part of the opaque meal, but a small quantity generally remains scattered through the pelvic colon for many days or even weeks.

An X-ray examination after an opaque enema gives the only means of recognising the exact anatomical condition present in megacolon. It is, however, essential to watch the fluid being run in, as it is otherwise impossible to interpret a radiograph owing to the large amount of overlapping of different segments of the bowel caused by the enormous dilatation of the pelvic colon, the uppermost loop of which is often mistaken for the splenic flexure. The fluid is seen to run straight upwards through a greatly dilated rectum and pelvic colon to the left dome of the diaphragm. Even if the rectum is not found to be dilated on digital examination; it is always distensible and no resistance in the passage of the enema into the pelvic colon is encountered; it is, in fact, often impossible to recognise where the rectum ends and the pelvic colon begins. After reaching the diaphragm, the fluid passes downwards again, but often not until it has made a more or less complicated loop, which may reach the right dome of the diaphragm in front of and above the liver. It finally reaches the left brim of the pelvis, where it passes upwards again along the iliac and descending colon to the splenic flexure and thence without difficulty to the cæcum. The splenic flexure, together with that of most of the transverse colon and all of the descending colon and iliac colon, is entirely obscured by the pelvic colon, which lies in front of it. Very large quantities of fluid are required to visualise the whole colon, and the pelvic colon alone

may have a capacity of 6 to 12 pints. The colon in children may hold as much as 4 to 6 pints, and in babies 1½ to 2 pints.

The size of the colon, as shown in a radiograph taken after the injection of an opaque enema, is not an indication of its actual size nor a measure of its tonicity, but an indication of its distensibility. Even if the fluid is injected at a pressure insufficient to cause discomfort, the size of the various segments is often much greater than what it is when seen with the sigmoidoscope or after an opaque meal. The radiographic appearance after an opaque enema does not correspond with the condition present immediately before it is given, because the walls of the colon relax in order to allow more and more fluid to enter until the maximal size which has been present at any recent time is attained. This explains why the pelvic colon in a case of megacolon, in which more or less complete relief has followed treatment, often appears to be as large as ever when examined after an opaque enema, though any abdominal distension present before the treatment may have disappeared and an opaque meal and sigmoidoscopic examination show no abnormality.

Prognosis.—Megacolon is compatible with perfect health. The majority of my patients came on account of nothing more than constipation, which was generally no more severe than that occurring in many individuals with no organic disease of any kind; in four it was accidentally discovered in the course of a routine investigation on account of abdominal symptoms caused by some other condition. Toxic symptoms are rare unless aperients have been taken in excess. Only in exceptional cases, in which the X-rays show that severe stasis occurs in the cæcum and ascending colon as well as in the pelvic colon, may true intestinal toxæmia occur. As 16 out of the 36 private cases were over 50 and an additional 9 were over 40 when I first saw them, although the condition had presumably been present for many years, if not from infancy, megacolon does not as a rule shorten life.

Only three of my patients died directly as a result of the intestinal condition—all after operation; a fourth patient died after excision of a carcinoma, which had developed in the dilated colon. Of the three fatal cases a woman of 22 died after colectomy in 1912, and a boy of 5 died after ileo-sigmoidoscopy performed as a preliminary to colectomy in 1914. With our present knowledge of the condition both of these patients could have been relieved by non-surgical means. The third case was a man of 55, who died after an operation for volvulus of the cæcum five years after I saw him.

All the children I have seen since the war with megacolon are developing normally and appear to be none the worse either physically or mentally for having had a dilated colon.

Complications.—*Volvulus.*—In a small proportion of cases the patient complains of sudden attacks of very severe pain with abdominal distension. Slight attacks, in which the pain is not very severe and the distension is slight, occur much more frequently; they are probably of the same nature as the severe attacks and are caused by the twisting of a loop of the dilated pelvic colon. Both types of attack may last a few hours or a few days, and almost always subside spontaneously.

Carcinoma.—In one of my patients—a man of 64—a carcinoma had developed in the dilated colon.

Treatment.—The main object in the treatment of megacolon is to lessen the resistance offered by the closed anal sphincter to the passage of fæces

and gas. Rapid stretching of the sphincter is not as a rule effective, as it quickly contracts again to its original state. For a permanent result to be obtained the postural tone of the muscle fibres of the sphincter must be permanently reduced. This can best be attained by the use of a conical ebony bougie, which is passed every morning just after the first attempt to open the bowels has been made. The bougie is pushed slowly in as far as it will go without causing discomfort and kept in position for half an hour. Patients soon learn to pass it for themselves, and the mother or nurse can pass it for children. A second attempt to defæcate is made immediately afterwards. At the end of about a week the bougie need be kept in position for only a quarter of an hour; at the end of a month it is passed on alternate days, then once a week, and finally it is used only from time to time if a slight return of symptoms should occur.

When a child with megacolon comes under treatment there is generally a large accumulation of fæces in the pelvic colon and in about 50 per cent. of cases in the rectum as well. The latter cases are easier to treat, as when the rectum is empty and a secondary kink has developed at the pelvi-rectal flexure, treatment of the anal achalasia does not help until the pelvic colon has been kept comparatively empty for some time so that its contents can pass without difficulty into the rectum. In adults such an accumulation is less frequently found, though in neglected cases and in all of the comparatively small number which have come to autopsy, huge quantities of fæces are present. In both children and adults there is always a very large accumulation of gas in the dilated segment of bowel. Before any permanent improvement can be attained, the fæces and gas must be evacuated as completely as possible. Aperients are quite useless, and enemas are not always effective, as a good deal of the water injected is often retained. In neglected cases in children the best results are obtained by evacuation under a general anæsthetic, partly by lavage with simultaneous abdominal kneading and partly by the finger. The fæces are generally soft, but sometimes a secondary cause of obstruction is present in the form of a solid ball of fæces, which acts as a ball-valve in the rectum and has to be broken up and removed bit by bit under an anæsthetic before the colon can be emptied.

After the colon has been evacuated and the resistance offered by the anal sphincter reduced, the patient is generally able to get his bowels satisfactorily opened every day. No aperient should be given, but it is wise to prevent the fæces from becoming hard by means of liquid paraffin. In many cases no further treatment is required. Sometimes, however, especially if the dilatation has been excessive, there is still a tendency for fæces to accumulate in the pelvic colon in spite of the bowels being opened daily. It is then necessary to give an enema perhaps once a week or once a month. In some cases the best results are obtained with a very large enema, as much as 8 or 10 pints being run in under low pressure; in others, most of the water is retained when large quantities are given, and quite satisfactory results are obtained with a single pint.

When attacks of pain and distension, presumably caused by a partial volvulus, recur in spite of treatment, immediate relief can often be obtained by the passage of a long flatus tube with the patient in the knee-elbow position. If this fails and the pain is severe, morphine and atropine should be injected. Relief almost always follows, but if the attacks are frequent and

severe the dilated loop forming the volvulus should be excised in the free interval.

Such operations as colostomy, ileo-sigmoidostomy and colectomy, which were formerly performed for megacolon, had a very high mortality and rarely led to any appreciable improvement, as the primary seat of obstruction—the anal canal—was left untouched. Various operations on the sympathetic nervous system have been performed with the object of reducing the tone of the anal sphincter, but this object can be very much more simply attained by local treatment. The operation has the further disadvantage of being invariably followed in males by permanent loss of ejaculatory power and consequent sterility.

It has recently been discovered that complete relief may follow spinal anæsthesia, and it is probable that the good effects of sympathectomy were really the result of the anæsthetic used for diagnostic purposes or for the operation. It seems likely that spinal anæsthesia will in the future replace all other methods of treating megacolon.

A. F. Hurst.

ACUTE INTESTINAL OBSTRUCTION

Acute intestinal obstruction is a condition in which the passage of the contents along the intestinal canal is more or less suddenly obstructed either completely or in greater part. Only mechanical causes of intestinal obstruction will be dealt with in this place, conditions of paralysis or spasm causing obstruction being considered elsewhere.

Ætiology.—The causes of acute intestinal obstruction are numerous, and may best be considered under (1) causes within the lumen of the bowel, (2) causes in the wall of the bowel, and (3) causes outside the bowel, while there are two additional conditions—intussusception and volvulus—which do not come under any of these categories.

1. Causes within the lumen of the bowel giving rise to acute obstruction are gall-stones, fæcal accumulations, and, very rarely, true foreign bodies.

Large gall-stones enter the intestine through a fistula between the gall-bladder and duodenum or, more rarely, some other part of the intestinal canal. Gall-stones are generally passed spontaneously; when this does not occur the site of impaction is often the lower part of the ileum near the ileo-cæcal sphincter.

Fæcal accumulation is a common cause of an acute termination to a case of chronic obstruction, but even without any previous narrowing it may cause obstruction. In such cases the fæcal mass may be enormous in size and of a stony hardness; it leads more frequently to the pseudo-diarrhœa of partial obstruction than to complete obstruction.

2. Causes in the wall of the bowel give rise in most cases to chronic rather than acute obstruction; the commonest of such narrowings are those due to cancer. These conditions are discussed elsewhere, and it is only their liability to an acute termination which needs consideration here. Such a final catastrophe may result from the impaction of fæces, or acute paralysis of the intestinal wall with or without peritonitis may develop. Congenital stricture is a rare cause of acute intestinal obstruction in early infancy;

apart from stricture of the rectum, the commonest site is in the duodenum, just above the entrance of the bile-duct, or in connection with Meckel's diverticulum.

3. The most common cause outside the intestine is strangulation of a portion of intestine by congenital or adventitious bands, diverticula or peritoneal adhesions. Such bands may result from old tuberculous or inflammatory disease, or may be a sequel to a laparotomy. They may be produced by the adherence of normal structures, such as the omentum, Fallopian tube or appendix to other abdominal organs, or may result from the presence of a persistent Meckel's diverticulum. The latter may remain attached to the umbilicus, or its free end may become adherent. Such bands may obstruct by bridging across a portion of bowel, or a knuckle of bowel may become twisted round or under them, or, if the band is not long, mere kinking at its point of attachment may be sufficient to obstruct the lumen. Internal herniæ may give rise to strangulation and intestinal obstruction; their commonest sites are congenital or acquired slits or tears in the mesentery or omentum, one or other of the normal peritoneal fossæ, or, more rarely, the foramen of Winslow or congenital or acquired apertures in the diaphragm. The peritoneal fossæ into which such internal herniæ may pass are situated in the neighbourhood of the duodeno-jejunal flexure, in the peri-cæcal region, and in the root of the pelvic mesocolon.

4. *Intussusception.*—By intussusception is meant the passage of one segment of intestine into another immediately below. When this occurs a tumour is formed consisting of three layers, the outermost or intussuscipiens being the portion of bowel into which invagination is occurring, and the inner two constituting the intussusceptum, which therefore consists of an entering layer and a returning layer. Between these latter is the strangled mesentery, interference with the vessels of which speedily occurs and induces changes in the intussusceptum. The apex is the distal part of the intussusceptum, and the neck the narrow part where the returning layer turns to become the sheath or intussuscipiens.

The chief cause of intussusception is undue enlargement of the intestinal lymphatic tissue producing irregular muscular action, aided no doubt by an unusually long mesentery, and by an atonic condition of the ileo-cæcal sphincter. All these three factors, particularly the first, are most common in early childhood, and intussusception is consequently rare at other ages; 70 per cent. of cases occur in infants under a year old. In adults an intestinal polypus or carcinoma is often the starting-point of the invagination, which generally differs from that occurring in infants by being chronic instead of acute.

Various forms of intussusception occur, of which the ileo-cæcal variety, with the ileo-cæcal valve as its apex, constitutes about 70 per cent. Enteric, colic, ileo-colic and multiple intussusceptions are less frequent. An intussusception always increases at the expense of the ensheathing layer, its apex remaining constant.

5. *Volvulus* is a condition in which a coil of intestine becomes twisted on itself around its mesenteric axis, leading to interference with its circulation and with the passage of its contents. It occurs most frequently in the pelvic colon and the ileum, but may affect the cæcum or any part of the intestine with a mesentery. It usually occurs late in life, is commonest in males, and

depends partly upon an abnormally shaped mesentery and partly upon loading of the loop from chronic constipation. The dilated coils above a chronic obstruction are especially liable to become twisted and so bring about an acute termination to the case.

Pathology.—In acute intestinal obstructions the conditions found fall mainly into two groups depending on (1) the occurrence of obstruction of intestine with a previously normal lumen, and (2) acute obstruction terminating a case of gradually increasing chronic obstruction.

1. In most cases in this group a portion of intestine is strangulated in addition to the obstruction to the lumen of the bowel, and consequently the condition of the intestine must be considered in three regions—namely, above the obstruction, below it, and in the strangulated coil itself. An exception occurs in the acute obstruction produced by an impacted foreign body, where, of course, there is no strangulation.

(*a*) The intestine above an acute obstruction is usually greatly distended, its walls are at first pale and thin, and later œdematous and purple in colour, and the extent of these changes rapidly increases upwards as the obstruction persists. The distended coils are full of fluid (partly the normal dammed-back secretion, partly an exudation of serum), and as the case progresses bacteria escape through the distended and paralytic coils, and lead to peritonitis. These changes are far more marked in small intestine obstruction than when the colon is affected.

(*b*) Below the obstruction the coils are, as a rule, empty, contracted and pale.

(*c*) As a result of circulatory interference, the strangulated coil itself becomes distended with effused blood and gas, the latter mainly CO_2, which cannot be absorbed. It is purple in colour, tense, œdematous and paralysed, and it exudes bloodstained fluid both into its lumen and into the surrounding peritoneum. If the strangulation is sufficiently severe to obstruct arteries as well as veins the coil becomes gangrenous in less than an hour. Such a coil is grey and loses its peritoneal sheen; it is flaccid and exudes free gas and stinking fluid into the peritoneum. This condition is, of course, irrecoverable, but in less complete strangulation the intestinal wall quickly returns to normal when the strangulation is released. A strangulated coil soon looses power to prevent the passage of bacteria, and if left alone its vessels inevitably become thrombosed, and its walls become gangrenous and ultimately perforate. The contents of an obstructed loop are profoundly toxic, the toxicity being greater the higher in the course of the alimentary canal the obstruction is situated.

2. When acute supervenes on chronic obstruction, the bowel has already had time to accommodate itself in some degree to the presence of narrowing of its lumen. The final blockage of the passage is most frequently due to impaction of fæces in the narrowed part, or kinking adhesion, volvulus or acute paralysis of the intestine above it. In such cases the already existing hypertrophy above the obstruction gives place to rapidly increasing distension, and as a result the intestinal circulation is interfered with, and gas, being no longer efficiently absorbed, collects within the bowel. The enteritis and ulceration usually present in some degree above a chronic obstruction rapidly increase, and perforation and consequent peritonitis speedily follow.

Symptoms.—The symptoms of acute intestinal obstruction vary to a

certain extent with the particular cause of the condition, but some of them are present in all cases. Of the general symptoms, pain, vomiting, constipation and collapse are the most important.

Pain is an early symptom and is very severe, in many cases a patient in perfect health being suddenly seized with an acute abdominal pain which doubles him up and never remits. At first the pain is stabbing in nature, but later he complains of exacerbations which are colicky in character, and which occasionally serve to localise the obstruction. If the case is allowed to progress until peritonitis supervenes, the continuous pain and tenderness associated with that condition are present in addition.

Vomiting, preceded by nausea and severe retching, usually comes on about an hour after the pain, but it may be delayed for 8 or 10 hours. Once it has begun it continues with increasing frequency, and from the second to the fourth day it becomes fæcal in character. The higher the site of the obstruction is situated in the bowel, the greater the vomiting and the sooner it becomes fæcal. Fæcal vomiting is not due to antiperistalsis, but is caused by the stagnant and excessive secretions of the portions of bowel above the obstruction, gradually extending upward until they overflow into the stomach and cause vomiting. The fæcal character is accounted for by the remarkable speed with which *Bacillus coli* and other organisms multiply in the stagnant contents.

Collapse is early and severe. The patient is prostrated, anxious, and restless, the pulse is rapid, small and thready, the temperature subnormal, and the extremities cold and clammy. The collapse is partly reflex from stimulation of the vagal and splanchnic nerve endings in the abdomen, and is partly due to loss of fluid from sweating and excessive intestinal secretion. A very important part is also played by the toxic intestinal contents; the higher in the bowel the obstruction is situated the greater is the toxicity of the stagnating contents.

Constipation is as a rule absolute, although the bowel below the obstruction may empty itself shortly after the onset of the pain and vomiting. Neither fæces nor flatus are passed, and enemata after washing away any fæcal material present in the bowel below are either retained or return slowly without force.

In addition to these cardinal symptoms the patient presents certain other important signs. The tongue is dry and the teeth are covered with sordes. The abdomen at first is not tender to touch, and sometimes pressure may relieve the pain. It is often not distended, though in some conditions, such as volvulus, the distension may be extreme. If acute obstruction supervenes on chronic obstruction visible peristalsis may be present, and the coils can be felt to harden under the hand. Occasionally a tumour is felt in the abdomen, especially in intussusception, where a sausage-shaped mass can frequently be felt. On auscultation intestinal sounds are present in increased intensity, and are high-pitched in character. If the case goes on until peritonitis supervenes the symptoms of that condition develop and consequently the abdominal picture changes. In acute intestinal obstruction the urine is scanty and highly coloured, and when the obstruction is low in the bowel it contains a great excess of indican. The viscosity of the blood is increased from loss of fluid; this probably accounts for the frequent cramp-like pains in the limbs.

Diagnosis.—The diagnosis of acute intestinal obstruction is usually easy, but the further differentiation of the site and nature of the obstruction, though sometimes fairly simple, is often impossible before operation. The history is of importance in deciding whether the acute symptoms have supervened on those of chronic obstruction, in which case similar but less severe attacks which were relieved by enemata or purgatives may have occurred. A previous history pointing to gall-bladder trouble, particularly if the onset of obstruction is somewhat less acute than usual, suggests gall-stone impaction.

Inquiry should be made for evidence of abdominal attacks suggesting appendicitis, salpingitis, or other conditions, which might produce bands.

The presence in an infant of a sausage-shaped tumour, which can be felt to harden and is situated usually in the upper abdomen, with tenesmus and the passage of blood and slime, acute attacks of colic causing the child to scream and to draw up its legs, with occasional vomiting, forms a characteristic picture of intussusception, and enables a confident diagnosis to be made in many cases. In doubtful cases, examination under anæsthesia may be required, and rectal examination may enable the intussusception to be felt.

In volvulus the onset is acute, but collapse may be absent. Vomiting is not frequent at first, but the characteristic feature is the rapid onset and extreme degree of distension. This distension may at first be localised and indicate the seat of the volvulus, but it soon involves the whole abdomen and may cause severe cardiac and respiratory embarrassment.

Distension implies interference with the blood supply and consequent deficient absorption of gas from the bowel; it is thus a valuable indication as to whether strangulation has taken place as well as intestinal obstruction.

The conditions from which acute intestinal obstruction has to be differentiated are numerous. The most important is hernia, and a careful examination of the hernial apertures should always be made. In some cases of small femoral herniæ in fat persons it is very easy to overlook the condition, and in the rare obturator hernia diagnosis is frequently only possible on opening the abdomen. Fæcal impaction is another important condition to be considered, particularly in view of the grave results of laparotomy mistakenly undertaken for its relief. The history of chronic constipation and the presence of hard or putty-like masses in the rectum or pelvic colon should prevent errors.

Peritonitis is often a source of difficulty. The extreme tenderness and rigidity, the absence of fæcal vomiting, the partial nature of the constipation at first, as well as the temperature, history, and silence of the abdomen on auscultation are distinguishing features. Difficulty may arise from conditions causing acute stimulation of the sympathetic nerve, such as torsion of the testicles, ovary, or omentum, or the passage of a renal or biliary calculus. Careful inquiry of the history, the characteristic distribution of pain in the colics, examination of the scrotum and vagina and of the urine will usually lead to a correct diagnosis. Further, in these conditions enemata generally result in passing of flatus, and the course of the disease does not follow the usual sequence of cases of acute intestinal obstruction. In acute pancreatitis the pain is localised in the epigastrium, while the constipation is usually not absolute.

Lead colic can be distinguished by the blue line on the gums, the history, the blood picture, the absence of fæculent vomiting, and the result of enemata; while a routine neurological examination will distinguish tabetic crises.

Rare conditions which may lead to mistakes are embolus or thrombosis of the superior mesenteric vessels. In embolus some cardiac lesion is usually present, and in thrombosis there may be evidence of cirrhosis, gall-bladder disease or thrombosis of other veins, while hæmatemesis and melæna are common in both conditions.

Prognosis.—Spontaneous cure is remotely possible in all cases of intestinal obstruction, but in the majority of cases, if operation is not undertaken, death occurs at varying intervals, the average being after 6 days. Once the obstruction has been relieved by operation recurrence is uncommon, excepting perhaps in cases due to adhesions following operation. Even when operation is undertaken acute intestinal obstruction has a grave outlook, depending partly on the length of time elapsing before operation and partly on the nature of the lesion present. Other conditions materially affecting the prognosis are the age and general condition of the patient, and the presence of toxæmia, septicæmia, peritonitis, or complicating conditions elsewhere.

Treatment.—Excluding cases of fæcal impaction the treatment of all cases of acute intestinal obstruction is immediate operation. The object of the surgeon is to locate the seat of the obstruction, and to relieve it as quickly as possible with the minimum of handling and exposure of the abdominal contents. When the abdomen is opened a collapsed portion of gut is sought, as it helps to localise the seat of obstruction. When found, the obstruction must be relieved in the simplest possible manner, by reducing a hernia, dividing a band, reduction of an intussusception by manipulation, removing a gall-stone, etc. If, however, the obstruction cannot be relieved, or if the bowel is too severely damaged to return to the abdomen, it is wise simply to establish drainage above the obstruction and to wait till the acute period is passed before undertaking further measures. In cases with much distension, where the obstruction is obviously in the colon, and where an exploration would entail considerable handling, the proper treatment is undoubtedly to perform a blind cæcostomy and to delay further procedures until the distension has been relieved. Apart from operation, saline solution should be given intravenously, by the continuous drip method to combat the loss of chlorides and fluid, and opium may be given to relieve pain once the diagnosis is established and operation agreed to. Gas-gangrene antitoxin (*B. welchii*) is of value in combating toxæmia, and helps to relieve distension. It should be given intramuscularly, the initial dose being 10,000 units, followed by 4000 units on the two next successive days.

APPENDICITIS

Ætiology.—The two sexes are affected equally. No age is exempt, but whereas acute appendicitis is more common in children, chronic appendicitis is more common in adults.

The appendix may become infected either by organisms spreading from the lumen of the cæcum or conveyed by the blood. In the former case, the

original infection may presumably come from infected food, but septic foci in connection with the teeth, tonsils and naso-pharynx are undoubtedly of more importance. The latter are also the chief sources of hæmatogenous infection.

The commonest organism is the *Bacillus coli communis*; next in order of frequency come streptococci and staphylococci. The proteus, tubercle and actinomycosis organisms are rare. Congenital or acquired abnormalities are present in a considerable proportion of cases. In the former the appendix is not fully descended, is of the infantile variety, or is twisted on itself. In the latter, there are adhesions or kinks caused by previous inflammation either of the appendix itself or of neighbouring organs; and in many cases the bands resulting from chronic intestinal stasis lead to kinking of the appendix. Obstruction to its lumen from any of these causes produces stagnation of its contents, and provides the necessary conditions for bacterial invasion. Foreign bodies are another cause, but they occur less frequently than might be expected. Intestinal worms, pins, and fruit pips and stones have all been met with, but by far the commonest foreign body is the so-called "appendicular concretion," formed of inspissated fæcal material moulded into shape by the appendix itself.

Acute Appendicitis

Pathology.—In catarrhal appendicitis the mucosa only is affected, but in the commoner diffuse type all the coats are involved, the organ being hyperæmic, rigid, tense, and swollen, and the mucous membrane being frequently ulcerated. Later the lumen of the appendix becomes filled with pus, and if there is obstruction, empyema of the organ results. Later still, local or general gangrene occurs, the most frequent sites being the tip or the base. Perforation is very liable to take place at any of these stages, leading either to a localised appendicular abscess or to generalised peritonitis. The chief factor in determining which of these two complications will occur is the virulence of the organism, since it requires time for the reaction of the peritoneum to come into play sufficiently to localise the results of perforation to the immediate neighbourhood. If the lumen of the appendix is obstructed by a stercolith, acute appendicular obstruction results, and the tension of decomposing fæcal matter within its lumen leads to rapid gangrene and perforation. In milder cases the inflammation tends to resolve, and the appendix may return to an apparently normal condition, but if the attack has been at all acute, either adhesions or narrowing of the lumen generally remain, leaving it far more liable to further attacks of inflammation. If perforation and abscess formation occur and operation is not undertaken, spreading peritonitis results. Suppurative pylephlebitis may result from spread of infection along the mesenteric veins either with or without perforation of the appendix.

Symptoms.—In nearly all cases the following symptoms are present, though they may vary in degree—(1) sudden abdominal pain, (2) pyrexia, (3) increased pulse rate, (4) gastro-intestinal symptoms, (5) local signs.

1. *Sudden abdominal pain.*—The onset is usually sudden, the patient being seized with severe abdominal pain, often severe enough to produce collapse and vomiting, and often referred at first to the region of the umbilicus, particularly in children. Later the pain becomes more or less local-

ised to the right iliac fossa, and may be of considerable intensity. In the obstructive type of case, colicky pain marks the onset, unassociated with fever or increase of pulse rate, and continues until perforation results, or operation is undertaken. In very severe cases, especially in children, and where early gangrene occurs, the pain may be comparatively slight after the initial onset, and in other cases the affection may progress to abscess formation with relatively little pain. Such cases are, however, the exception, and the pain is usually a prominent symptom.

2. *Pyrexia* is almost always present at some time during the attack, except in cases of the obstructive type, where its absence is apt to lead to mistakes in diagnosis, but its height is no measure of the severity of the lesion in the appendix. There is sometimes a rigor at the onset, and the temperature in an average case varies from 100° to 102°, rarely higher. A rise only to 99° or 100° is not uncommon, but is important, as very few cases occur in which there has not been some pyrexia at some period of the attack. When a localised abscess has formed, and in very severe cases with perforation and generalised peritonitis, the temperature may be normal or subnormal throughout.

3. The *pulse rate* is usually increased and tends to continue to increase as the disease progresses. In cases of appendicular obstruction there may be no increase in the pulse rate until perforation has occurred.

4. *Gastro-intestinal disturbances* are almost invariably present. The tongue is furred and rapidly becomes dry. Vomiting is frequent. There is usually vomiting at the onset of the attack, and though this persists in the severe cases with peritonitis, it may pass off, but nausea usually continues. Constipation is the rule, and in the majority of cases is absolute. Diarrhœa is, however, by no means uncommon, indicating usually a pelvic position of the appendix, in which the inflammation spreads to and irritates the rectum. If the process is allowed to progress, complete constipation resulting from peritonitis and consequent paralysis of intestinal movements ensues. Even before this stage has been reached, auscultation over the region of the cæcum often reveals a complete absence of the usual intestinal sounds, which may be of considerable help in diagnosis.

5. *Local signs.*—There is usually no distension of the abdomen at the onset of the attack, but on inspection it will be seen that the lower abdomen moves less freely than the upper on respiration, and the right side less than the left. There is frequently hyperæsthesia of the skin in the right iliac fossa, and occasionally some œdema can be discovered by loosely picking up the skin and subcutaneous tissues between the fingers and comparing with the other side. There is great rigidity of the right rectus muscle, and this is probably the most important single sign; the rigidity is often too great to allow of any proper deep palpation. In addition to the rigidity there is great tenderness and pain on palpation, which has its maximum at Mac-Burney's point, situated at the junction of the outer and middle thirds of a line drawn from the anterior superior iliac spine to the umbilicus. In children the maximum pain and tenderness are often in the region of the umbilicus. In some cases an ill-defined mass can be felt in the right iliac fossa, and the longer the history, the more likely is such a mass to be present. It is constituted mainly of adherent coils of intestine and omentum surrounding the inflamed or perforated appendix. Rectal examination is often of

value, and in many cases a tender mass can be felt on the right side of the rectum, when none can be made out from above. Considerable irritability of the bladder may be present, especially with a pelvic appendix, and the urine, which is scanty, frequently contains albumin.

A blood count is occasionally of value for purposes of differential diagnosis, and usually shows a leucocytosis of from 15,000 to 20,000.

In many of the worst cases, some or all of these signs and symptoms may be absent, but with a careful examination and a clear history it is usually possible to reach a correct diagnosis.

In some cases an abnormally situated appendix gives rise to characteristic symptoms. With a retro-cæcal appendix, local signs in the right iliac fossa may be absent, there being instead great pain and tenderness in the loin, and rigidity without great tenderness of the right rectus. These cases are specially apt to develop subdiaphragmatic abscess, and later empyema. An appendix running down into the pelvis is apt to give diarrhœa and bladder irritability, local rigidity may be slight and a mass can usually be felt per rectum. An appendix running directly inwards may occasionally give rise to left-sided symptoms.

Course.—Where a correct diagnosis is made, early operation should be undertaken at once, for reasons to be discussed later, but if for any reason operation is delayed the case may take one of three possible courses.

(*a*) Gradual recovery may ensue, and in first attacks this will occur in a large number of cases. Improvement begins about the second or third day and the acute symptoms generally subside in a week. In such cases the patient is extremely liable to have further attacks, a liability which is increased in proportion to the degree of change which has occurred in the appendix.

(*b*) In many cases, as the result of ulceration or perforation of the appendix, the local symptoms not only do not disappear at the end of the first week, but persist and become aggravated. The temperature usually rises and there may be rigors, while at the same time a tumour becomes palpable in the iliac fossa. In some cases the abdominal wall may become œdematous and indurated, and the patient frequently begins to lose weight rapidly, to sweat profusely and to show all the signs of closed suppuration. If an operation be now performed, an abscess is found in connection with the appendix, having definite walls composed of adherent and matted intestine, omentum and parietal peritoneum. Such abscesses often contain large quantities of very foul-smelling pus, and if left alone may burst into the rectum or general peritoneum, or more rarely on to the surface, usually in the neighbourhood of the umbilicus. Spontaneous recovery may follow rupture into the rectum or on to the surface, but in the other cases death is almost certain to ensue.

(*c*) The third result of an unoperated attack of acute appendicitis, and by far the commonest cause of death in this disease, is generalised peritonitis. This may occur either from perforation of the appendix before limiting adhesions have had time to form, as in cases of the obstructive type, or it may occur without any perforation at all. In the latter case bacteria pass through the wall of the inflamed appendix and set up suppuration in the neighbourhood; if the resistance is poor, this involves the neighbouring peritoneum and ultimately leads to a generalised infection. In other cases

a localised abscess may form and later burst into the peritoneum, a result often precipitated by sudden exertion on the part of the patient, injudicious palpation, or the administration of aperients. The great danger of appendicitis, and one that can only be met by immediate operation in all definite cases, is that general peritonitis may occur from the very beginning, and its symptoms may be indistinguishable from those of the acute appendicitis itself. In the hands of competent abdominal surgeons, operation in the early stages is one of almost absolute safety, and in these circumstances any delay, with the shadow of possible peritonitis menacing the patient at any time, is quite unjustifiable.

Diagnosis.—As appendicitis is by far the commonest acute inflammatory condition occurring in the abdomen in people under middle age, it must always be thought of in the presence of acute abdominal disease. In a typical case, with acute onset of abdominal pain, generalised at first and later settling into the right iliac fossa, with vomiting, constipation and local rigidity and tenderness, the diagnosis is easy, but one or more of these signs may be absent, and in such cases it is well to remember that a single positive sign is worth several negative ones. The most constant single sign is tenderness on deep pressure in the iliac fossa, and if this is present even in moderate degree, the case must be carefully watched before a diagnosis of acute appendicitis can be safely discarded.

Rectal examination may reveal bulging of the rectal wall by an abscess, particularly with a pelvic appendix, which, if palpable, is extremely tender.

A general examination of the patient is essential in order to eliminate certain other conditions which sometimes lead to mistakes. Right-sided pneumonia may cause difficulty, as the onset is sometimes associated with considerable pain and rigidity in the right side of the abdomen, but as a rule the accompanying respiratory symptoms and signs, especially the rapid respiration, will prevent error. In children, contraction of the right psoas muscle with flexion of the hip may suggest an acute arthritis or even a psoas abscess, whilst a psoas abscess is occasionally mistaken for appendicitis. Of the abdominal lesions most likely to cause confusion the most difficult to differentiate is acute tubo-ovarian disease in women. In some of these cases, appendicitis coexists from spread of infection, and where doubt remains after a thorough pelvic examination it is safer to operate than to risk leaving a possible acute appendicular lesion.

In perforation of gastric or duodenal ulcers, the general shock is more profound, the rigidity is more general and board-like, and the pain is diffuse and not localised; in biliary, renal, and intestinal colic, the nature and distribution of the pain usually suffice to prevent mistakes. Twisting of a small ovarian cyst may be impossible to differentiate, but operation is called for in either case. In certain cases of typhoid fever the clinical picture may simulate appendicitis very closely. The relatively slower pulse and higher temperature, the constant headache, and the absence of any definitely acute onset, are of the greatest help in distinguishing, and a leucocyte count may be of considerable assistance, as leucopenia is present in typhoid fever in contrast with the leucocytosis of appendicitis.

Prognosis.—If left alone a considerable proportion of cases of acute appendicitis tend to recovery, but it is at present impossible to give an accurate prognosis of the course of any particular case within the first 48 hours. The

chief cause of death is peritonitis, and less often pylephlebitis, septicæmia, or pulmonary embolism. Even if recovery from a first attack does occur, the patient is left with a far greater liability to subsequent attacks, and is in some danger of acute or chronic obstruction from the adhesions which so frequently develop. Successive attacks of appendicitis tend to be more severe, and a patient who has had two is almost certain to have further trouble.

With early operation the prognosis is extremely good, death being rare after operation within 36 hours. Even when operation is undertaken later in the attack, the prognosis is still good, unless general peritonitis has ensued, in which case the prognosis without operation is uniformly bad. A further great advantage of early operation is that drainage of the abdomen can be avoided in these cases, whereas in later operations drainage is frequently necessary with a consequent increased risk of post-operative hernia.

Treatment.—In acute appendicitis operated on within 36 hours of the onset, the mortality in the hands of competent surgeons is negligible, and since it is quite impossible to determine the course which any particular attack is going to take, there can be no doubt that when the diagnosis is definitely established, operation should be undertaken at once. Some surgeons are of opinion that when the case is seen later than 48 hours from the onset and is tending to improve, medical treatment should be undertaken until the attack has subsided, and the appendix should be removed during the quiescent period. Since operation in these cases is, with modern technique, very little more difficult or dangerous than in early cases, such a view has little to recommend it, since it condemns the patient to two tedious periods of sickness instead of one, and there is, in addition, the risk of the patient's natural objection to an operation, when he feels perfectly well, overcoming the advice he has been given and leaving him exposed to all the risks of a further attack. When peritonitis or localised abscess formation has occurred, there are no two opinions as to the necessity of operation. If, for any reason, operation is impossible or refused, the patient should be kept in the Fowler position, should have nothing but water by mouth, and may be given morphine to diminish both pain and intestinal movement, provided always that the question of operation has been finally and definitely decided. Under no circumstances should a purge be given, as there can be no doubt that in far too many cases purgation is the direct cause of perforation.

Where an appendicular abscess has developed, it was formerly held that the abscess should be drained and the appendix removed subsequently. Modern surgical opinion is in favour of doing both at one operation, and in the hands of an experienced operator this procedure is undoubtedly best, but where skilled surgical aid is not available, simple incision and drainage of the abscess meet the immediate emergency.

E. G. Slesinger.

Recurrent Subacute Appendicitis, Chronic Appendicitis and Appendicular Dyspepsia.

At one time I diagnosed chronic appendicitis with confidence, and regarded it as a common cause of abdominal symptoms. In recent years I have diagnosed it with less and less confidence, and am now doubtful

whether such a condition really exists. I have seen hundreds of patients who have had their appendix removed for "chronic appendicitis" without the slightest benefit, and I am inclined to think that there is no justification for performing appendicectomy unless there is a history of subacute attacks, however slight. A considerable proportion of patients suffering from colon spasm and muco-membraneous colic and other abdominal neuroses and abdominal allergy, as well as from chronic cholecystitis, have their appendix removed without benefit before a correct diagnosis is made. Perhaps five per cent. of the patients, who ten years ago would have had their appendix removed for "chronic appendicitis," have recurrent subacute appendicitis and will benefit from appendicectomy. But there is no longer any excuse for ascribing symptoms to a "long," "kinked," "obliterated," "adherent," or "controlling" appendix. Symptoms are not likely to disappear permanently after appendicectomy unless the appendix contains pus or shows other definite signs of inflammation on naked-eye examination.

Symptoms.—A diseased appendix may give rise to gastric symptoms, accompanied by constant discomfort or short attacks of pain in the right iliac fossa. Epigastric pain, which may radiate downwards to the umbilicus or below, and occasionally towards the right iliac fossa, occurs after meals. The time of its onset is very irregular. Most commonly it occurs immediately after meals, but occasionally it may be delayed for 2 or 3 hours. It is at the most only slightly relieved by alkalis, and food rarely gives even momentary relief. It is aggravated by fatigue to a greater extent than is the case with the indigestion of gastric and duodenal ulcer and gall-bladder disease. The degree of discomfort varies from time to time; it is rarely completely absent and may sometimes be sufficiently severe for the patient to go to bed. Nausea is common and is often present in the absence of vomiting. Vomiting may occur, especially after food and when the pain is severe, but it gives much less relief than in gastric ulcer. Heartburn and acid regurgitation are uncommon. Hæmatemesis may occur from an acute gastric or duodenal ulcer secondary to the appendicular infection, which is also occasionally associated with a chronic gastric or duodenal ulcer. I have several times seen lasting benefit follow the removal of the appendix after an acute attack in a patient with a chronic ulcer, which had presumably been kept active hitherto by the presence of latent disease in the appendix.

Tenderness is generally more marked in the right iliac fossa than in the epigastrium, even when there is no spontaneous pain in the former situation. Occasionally the localised tenderness can be discovered only when pressure is exerted directly over the appendix after it has become visualised with the X-rays. In many cases pressure in the right iliac fossa leads to no local pain, but to discomfort in the epigastrium, sometimes with nausea, exactly simulating the spontaneous symptoms. Constipation is commonly present. In rare cases there may be chronic diarrhœa, but more frequently a form of pseudo-diarrhœa, in which frequent small stools are passed owing to irritation of the rectum by a chronically inflamed appendix situated in the pelvis. Pelvic appendicitis may also lead to irritability of the bladder with frequent micturition, and in women to dysmenorrhœa.

An operation is not justifiable for chronic appendicitis, unless the diagnosis has been confirmed by means of the X-rays and, if possible, by Bastedo's inflation sign. The appendix can be visualised in almost all normal individuals

and in about 80 per cent. of cases of appendicitis, and its discovery in the pelvis or immediately under the liver may explain anomalous symptoms. When the appendix is inflamed, all or part of it, especially the base or the tip, is found to be the point of maximum tenderness, definitely more tender than the end of the ileum or the cæcum. By manipulating the cæcum so that the position of the appendix in the abdomen is altered, the tender point moves with it. In some cases pressure on the appendix produces epigastric discomfort, either with or without local tenderness. Indirect evidence of appendicitis is occasionally afforded by the presence of ileal stasis, and by the recognition of adhesions in the right iliac fossa, which are most commonly due to previous attacks of acute or subacute appendicitis.

On inflating the colon with air through a tube introduced into the rectum generalised discomfort is felt in the lower part of the abdomen. Bastedo's sign is the production under these conditions of localised pain in the right iliac fossa with increased tenderness, sometimes associated with or even entirely replaced by epigastric discomfort. This is present in a large proportion of cases, but never in salpingitis, ureteral calculus, gall-bladder disease or other conditions, which might simulate chronic appendicitis. The inflation should be carried out during the X-ray examination, as it raises a pelvic cæcum and brings the appendix within reach of the palpating fingers. It also unravels confusing pelvic shadows and makes it possible to decide to what extent adhesions are present in connection with the terminal ileum, cæcum and appendix. If inflation fails to raise a pelvic cæcum and appendix into the abdomen, the X-ray examination should be repeated with a full bladder, which always brings them within reach of abdominal palpation except in the very rare cases in which they are fixed in the pelvis.

If repeated attempts fail to visualise the appendix it is probable that its mouth is obstructed ; in the presence of suspicious symptoms and tenderness in the ileo-cæcal angle the absence of an appendicular shadow favours the diagnosis of appendicitis. In such cases Bastedo's sign is also negative, as it depends upon distension of the appendix itself, which is only possible when barium can enter it.

Treatment.—Recovery should follow the removal of a grossly diseased appendix, but it is not infrequent for the symptoms to persist for a time or recur after the operation, especially if the disease is associated with some visceral neurosis or with chronic gastritis, gastric or duodenal ulcer, chronic typhlitis or chronic cholecystitis. Such associated conditions require attention both before and after the operation, and if the gall-bladder is diseased it should be removed at the same time.

ARTHUR F. HURST.

DISEASES OF THE LIVER

TESTS FOR HEPATIC FUNCTION

The most practically useful tests for hepatic efficiency in cases of suspected liver disease with or without jaundice are the lævulose tests, the hippuric acid test and the serum choline esterase test. For the lævulose tests 50 g.

of lævulose are taken in 100 c.c. of water on an empty stomach: the blood sugar is estimated immediately before and one and two hours later. Normally the first hour rise is between 0 and 20 mgrm. per 100 c.c.; at the end of the second hour the figure should fall within 5 mgrm. of the fasting figure. A combined rise of more than 25 mgrm. is suspicious, and of more than 30 mgrm. is certain evidence of hepatic insufficiency. If the fasting blood sugar is below 80 mgrm. or all the figures are above 120 mgrm., no definite conclusions can be drawn from the test. This test has recently been improved by substituting the estimation of the lævulose in the blood for that of the total blood sugar.

The hippuric acid test depends on the fact that in hepatic disease the power of the liver to conjugate benzoic and amino-acetic acids to form hippuric acid is reduced. The hippuric acid is estimated in the urine.

In hepatic disease there is also a diminution in the serum choline esterase, an enzyme which destroys acetylcholine with the formation of choline and acetic acid. The esterase is estimated by measuring the amount of CO_2 liberated when acetylcholine is added to a mixture of the blood serum and Ringer's solution; the bicarbonate of the latter reacts with the acetic acid formed to set free CO_2.

In considering the diagnosis of jaundice van den Bergh's reaction for excess of bile-pigment in the blood will be described, and the direct investigation of the bile obtained by means of a duodenal tube will be considered in connection with disorders of the gall-bladder and bile-ducts.

JAUNDICE

Definition.—Jaundice is the condition caused by the presence of bile-pigment in the blood, which manifests itself clinically by yellow coloration of the conjunctivæ and skin.

Ætiology and Pathology.—All cases of jaundice may be divided into three groups—hæmolytic jaundice, hepatic jaundice and obstructive jaundice.

(*a*) Hæmolytic Jaundice.—In hæmolytic jaundice bilirubin is produced in excess from hæmoglobin set free in the general circulation by the destruction of red cells as a result of abnormal fragility, as in acholuric jaundice, or of the presence of hæmolytic toxins in the blood. The hæmoglobin set free is broken down, and bilirubin is formed by the action of the endothelial cells of the spleen, and to a less extent the similar endothelial cells of Kupffer, which lie along the portal capillaries adjacent to the bile capillaries of the liver, and the endothelial cells of other organs. The excess of bile-pigment in the blood is thus formed quite independently of the glandular cells of the liver.

(*b*) Hepatic Jaundice.—This includes the toxic and infective jaundice described under the headings acute and subacute necrosis of the liver (p. 695) and infective hepatitis (p. 698) respectively. The jaundice is the result of damage to the liver cells which are unable to convey the bile-pigment from Kupffer's endothelial cells into the bile capillaries; the pigment consequently passes to the hepatic vein and thence into the general circulation.

(*c*) Obstructive Jaundice.—In obstructive jaundice bile excreted by the hepatic cells is reabsorbed by the hepatic blood capillaries, together

perhaps with the lymphatics, owing to the rise in pressure caused by obstruction of the bile-ducts. The obstruction may occur (1) within the ducts, or it may be due to (2) changes in their walls or (3) pressure from without.

1. *Obstruction within the ducts.*—This is almost always due to gall-stones. In very rare cases a hydatid cyst has ruptured into a duct, which becomes obstructed by a piece of membrane or a daughter cyst, or a round worm has entered the common bile-duct from the duodenum.

2. *Obstruction due to changes in the walls of the ducts.*—Congenital obliteration of the bile-ducts is a rare cause of icterus neonatorum (p. 688). An acquired stricture may result from accidental injury of the common bile-duct during operation. Catarrhal jaundice is due to the obstruction produced by inflammatory swelling at the mouth of the common bile-duct. Infective and suppurative cholangitis also lead to jaundice, but in some cases the obstruction to the ducts is associated with changes in the liver cells, which are in part responsible for the production of the jaundice. Primary carcinoma of the hepatic and common bile-ducts and biliary papilla give rise to jaundice.

3. *Pressure on the ducts from without.*—Malignant tumours of the liver and very rarely gummata and hydatid cysts give rise to jaundice by pressing on the intrahepatic branches of the bile-ducts; if some of the latter escape, bile still passes into the duodenum from other parts of the liver and the fæces remain coloured. The tumour may also project into the portal fissure and give rise to jaundice with colourless stools by pressing upon the hepatic ducts or common bile-duct.

Enlarged glands in the portal fissure may cause jaundice by pressure upon the ducts. The most common cause is primary or secondary cancer of the liver, as these glands drain the liver, but not the other abdominal viscera or peritoneum; for the same reason they rarely become tuberculous. They are very rarely enlarged in Hodgkin's disease and never in syphilis.

Jaundice may occur in cancer of the stomach, even when no secondary deposits are present in the liver or in the glands in the portal fissure. This is due to the pressure of glands in the neighbourhood of the head of the pancreas, or to direct spread of the growth into the lesser omentum, where it compresses the common bile-duct and may invade its walls.

Jaundice is produced by obstruction of the common bile-duct when chronic pancreatitis occurs in an individual in whom the duct is embedded in the head of the gland. It is generally present in cancer of the head of the pancreas, but very rarely with a pancreatic cyst or calculus.

Symptoms.—Jaundice appears first in the conjunctivæ and then successively on the face, neck, body and limbs. The mucous membrane of the lips and palate becomes yellow very soon after the conjunctivæ. In chronic obstructive jaundice the pigment in the skin becomes dark green. In a small proportion of very chronic cases xanthoma develops, but this condition is more common without jaundice (p. 1468). The patches consist of cholesterol, which the blood in jaundice contains in excess. In chronic jaundice there is a tendency for telangiectases to develop over the body and face; they may disappear at the same time as the jaundice. Purpura and hæmorrhage from mucous membranes, especially the nose and gums, may occur.

The urine becomes bile-stained before the conjunctivæ and skin, the interval being sometimes as long as 24 hours, but it generally returns to

normal before the yellow colour of the skin has disappeared. The urine may be yellow, olive, dark brown or even black. The colour can be distinguished from that in urobilinuria, hæmaturia and melanuria, and that produced by rhubarb, senna, santonin and chrysophanic acid by Gmelin's test for bile-pigment.

When obstruction to the bile-ducts is complete, no bile reaches the intestines and urobilin is absent from the urine; when the obstruction is incomplete, decomposition of the bile which reaches the intestines may occur and urobilinuria results. Bile-salts are only present in the urine for the first few days. Their disappearance is due to the fact that they are only produced in very small quantities, being constantly reabsorbed from the bowel and then re-excreted; when the bile-ducts are obstructed the kidneys rapidly excrete all the bile-salts present in the blood. In chronic obstructive jaundice bile-stained casts are almost always present in the urine, and less frequently albuminuria occurs. The urine often reduces Fehling's solution owing to the presence of glycuronic acid.

The fæces are bulky and often extremely offensive. When the obstruction is complete they are clay-coloured, owing partly to the absence of stercobilin and partly to the presence of excess of fatty acids and soaps which require the presence of bile for their complete absorption, and of neutral fat if the pancreatic duct is simultaneously obstructed (p. 688). Loss in weight results, and the excess of undigested food which reaches the colon is likely to cause excessive bacterial decomposition. This may lead to intestinal intoxication if the hepatic cells are damaged and their antitoxic action impaired.

The sweat may contain bile, which is also sometimes present in the tears and in the milk; but the saliva, cerebro-spinal fluid and mucus of the alimentary canal are free from bile, although the salivary glands and other organs are deeply bile-stained. The sputum in pneumonia and the effusion in pleurisy and peritonitis contain bile-pigments. The blood plasma is tinged with bile. Coagulation is considerably delayed in obstructive jaundice owing to deficiency of prothrombin. This is a result of lack of fat-soluble vitamin K ("Koagulation vitamin"), too little of which is absorbed when bile is absent from the small intestine.

In jaundice of recent origin the pulse is slow as a result of the presence of bile-salts in the blood. Pruritus occurs in about 20 per cent. of cases, especially when the jaundice is deep; it may be very severe and interfere with sleep. It is not directly due to the jaundice, as it may occur before the jaundice appears and continue after its disappearance; when present before the jaundice, it may subside with the onset of the latter, and it has also been observed in association with gall-stones when no jaundice was present.

The yellow vision or xanthopsia of jaundiced patients is less marked than that caused by santonin, and is rarely sufficiently obvious for the patient to mention is unless directly asked.

Diagnosis.—(*a*) RECOGNITION OF JAUNDICE: VAN DEN BERGH'S REACTION.—Bilirubin is normally present in the blood. Just as the kidneys in diabetes do not excrete sugar until the concentration in the blood has reached the leakage-point, which is considerably higher than the normal concentration, so no bilirubin passes into the urine until the concentration

in the blood has risen from the normal of 1 in 250,000 to the leakage-point of 1 in 50,000. About the same concentration is required to cause jaundice, but the appearance of a trace of bile-pigment in the urine is easier to recognise with certainty than the first trace of pigmentation of the skin or conjunctiva. Moreover, the pigmentation is somewhat slower to develop, and it remains for a time after all pigment has disappeared from the urine.

Hijmans van den Bergh has shown that excess of bilirubin in the blood can be recognised by a colour reaction, now commonly known as van den Bergh's test, which is given by Ehrlich's diazo reagent. The *direct reaction* may be "prompt," the maximum being reached within 30 seconds; it may be "delayed" for 1 to 15 minutes or be entirely negative; or it may be "biphasic," giving a slight prompt reaction, followed after a delay by gradual deepening of the colour. The *indirect reaction*, obtained after precipitation with alcohol so as to bring the bile into alcoholic solution, is always prompt.

With van den Bergh's test it is possible to distinguish two different forms of bilirubin. The direct reaction is prompt when the bilirubin is reabsorbed into the blood after it has been excreted by the hepatic cells in cases of obstructive jaundice, but is negative or delayed when the excess of bilirubin is a result of over-production, as in hæmolytic jaundice; it is negative, delayed or biphasic when the jaundice is due to inability of the hepatic cells to excrete it, as in toxic and infective hepatic jaundice.

By means of van den Bergh's test it is also possible to recognise latent jaundice. Thus the hyperbilirubinæmia present in pernicious anæmia gives a positive indirect reaction, although there is no jaundice except in occasional acute hæmolytic crises. Excess of bilirubin in the blood at a concentration below the leakage-point may also result from a very slight degree of biliary obstruction, such as may occur with a stone in the ampulla of Vater and in some cases of cirrhosis and of secondary carcinoma of the liver; it is recognised by giving a positive direct van den Bergh's reaction in spite of the absence of jaundice and of bile from the urine. In cases of progressive obstructive jaundice a positive direct reaction may be given at a stage before jaundice develops and bile appears in the urine, and still longer before any change is noticed in the stools.

(*b*) Differential Diagnosis of the Cause of Jaundice.

1. *Age, sex and history.*—Transient jaundice is common in the newly born (p. 688). Obstructive jaundice may result from congenital obliteration of the bile-ducts (p. 734) and congenital syphilis (p. 713). Severe jaundice in infants may be familial (p. 688). Mild infective jaundice may occur sporadically or in epidemics among infants; it is identical with the catarrhal jaundice of older children and adults. Epidemics of very fatal jaundice were formerly common in lying-in hospitals; sporadic cases still occur. The infection may enter by the umbilicus, which is red and swollen and may bleed, or by the alimentary tract; jaundice appears about the fifth day and is accompanied by high fever and severe septic symptoms. Hæmorrhage may occur from the alimentary tract or kidneys.

Jaundice occurring in childhood or before the age of thirty is generally catarrhal. After thirty gall-stones become a more common cause, especially in women, and after forty cancer is the most common cause in both sexes. Jaundice developing in pregnancy should raise a suspicion of acute necrosis of the liver. When more than one member of a family are affected, an

infection, such as spirochætal jaundice, or a toxæmia is probably the cause in acute cases; in chronic cases acholuric jaundice should be considered.

In jaundice of obscure origin the possibility of a toxic origin should be remembered, and inquiries made whether the patient has recently received treatment with organic arsenical preparations, atophan, etc.

2. *Colour.*—In hæmolytic anæmia the skin has a characteristic lemon-yellow colour, though the conjunctivæ are unaffected. In acute and sub-acute hepatic necrosis, such as the toxic jaundice caused by arsenobenzene, the skin assumes a very bright yellow colour, which is quite distinct from that of ordinary jaundice caused by obstruction of the bile passages. The former is probably produced by the form of bilirubin which gives only an indirect van den Bergh reaction, and the latter is produced by the form which also gives a positive direct reaction. A dirty yellow or greenish-yellow colour occurs only in chronic and more or less complete obstructive jaundice.

3. *Course.*—Jaundice of short duration is generally catarrhal or due to the passage of a gall-stone. Obstructive jaundice, which progresses until it becomes extremely deep, suggests cancer or chronic pancreatitis, whilst chronic jaundice, which varies from time to time, and intermittent jaundice are generally due to a stone in the ampulla of Vater, but may also be due to cancer of the ampulla of Vater.

4. *Condition of the gall-bladder.*—Enlargement of the gall-bladder indicates obstruction of the cystic or common bile-duct, though the former is not likely to be associated with jaundice. The enlargement is present in over 90 per cent. of cases in which obstruction is due to causes other than gall-stones, but in only 20 per cent. of cases of calculous obstruction. This difference is known as Courvoisier's law, and is due to the contraction of the gall-bladder caused by chronic inflammation in cholelithiasis, in which, moreover, the obstruction is often incomplete.

5. *Condition of the liver.*—Jaundice associated with great enlargement of the liver is generally due to growth if it is irregular, and to chronic obstruction of the common bile-duct if the liver is smooth; the irregular enlargement due to syphilis is less extreme, and, like that due to hydatid cysts or an abscess, is rarely associated with jaundice. The presence of ascites points to a growth or to cirrhosis, but the jaundice is generally more marked in the former.

6. *Examination of the stools.*—The presence or absence of stercobilin in the stools shows whether the common bile-duct is incompletely or completely obstructed. Slight excess of fatty acid and soap without any striated meat fibres or starch occurs in uncomplicated jaundice; excess of neutral fat, as well as fatty acid and soap, together with striated meat fibres, points to obstruction of the pancreatic duct. Complete absence of both bile and pancreatic juice from the intestinal contents indicates obstruction of the common bile-duct by a growth. Incomplete obstruction of the bile-ducts without interference to pancreatic digestion points to gall-stones, catarrhal jaundice or chronic pancreatitis.

7. *Pain.*—Constant pain suggests growth, attacks of pain gall-stones, and absence of pain catarrhal jaundice, acute or subacute necrosis, infective hepatitis or chronic pancreatitis; but many exceptions to this general statement occur.

8. *Syphilis.*—Active signs of syphilis or scars of old lesions indicate the possibility of a syphilitic origin, or of poisoning by an organic arsenical preparation which a patient may be having for syphilis without his own doctor's knowledge.

Treatment.—The treatment of jaundice is the treatment of the condition which causes it. The subject, therefore, requires no further consideration here, except for the pruritus and tendency to hæmorrhage, which are results of the jaundice itself. Thyroid, ½ gr. three times a day, and fractional doses of calomel may give relief to the pruritus, which is also helped by a warm alkaline bath, or moistening the irritable parts of the skin with 1 in 40 carbolic acid, 1 in 50 ichthammol, or 1 in 70 solution of menthol in spirit. The tendency to hæmorrhage can be controlled by the administration of vitamin K and bile-salts by mouth. Calcium, which is present in the blood in normal amount, is without effect.

Simple Jaundice in Infants (Icterus Neonatorum)

Ætiology.—Simple jaundice occurs in about 50 per cent. of infants, especially among the premature.

Pathology.—The number of red corpuscles is high in the newly born, but quickly falls during the first few days of life. The excessive blood destruction is associated with an excess of bile-pigment in the blood, as shown by van den Bergh's reaction, which gives a positive indirect but negative direct reaction in all new-born infants. The jaundice is therefore hæmolytic, and when death occurs from some independent cause nothing abnormal is found in the liver or bile-ducts.

Symptoms.—The jaundice generally begins on the second or third day of life; it increases in intensity for 2 or 3 days and then gradually diminishes until it disappears after 1 or 2 weeks, but occasionally it lasts for a longer period. The jaundice begins on the face and spreads over the whole of the body; unlike other forms of jaundice, the conjunctivæ are affected after the skin, and in mild cases they are not stained at all.

Diagnosis.—If the jaundice is slight, its presence can be recognised only by pressing the blood out of the cutaneous vessels, when the normal redness of the infant disappears and the yellow colour remains. Its short duration and the absence of enlargement of the liver and spleen distinguish simple icterus neonatorum from congenital obliteration of the bile-ducts, and the healthy condition of the infant distinguishes it from the infective forms of jaundice.

Prognosis and Treatment.—Rapid recovery always occurs, and no treatment is required.

Familial Icterus Gravis Neonatorum

The jaundice, which affects successive members of the same family, though the first-born often escapes, begins within a few hours of birth. The colour rapidly deepens till the skin is deep bronze. The infants are drowsy and take the breast badly. The stools are normal in colour. The urine is dark and contains urobilin and often bilirubin in excess. The liver and spleen are generally enlarged.

The quantity of bilirubin in the blood at birth is greater than normal; the blood contains no hæmolysin, but the cells show a slight increased tendency to hæmolysis.

In fatal cases death generally occurs within a few days and almost always within 3 weeks: *post mortem* nothing abnormal is found. Hampson has shown that complete recovery follows the injection of 15 c.c. of the mother's blood serum daily for 3 or 4 days into the infant's muscles.

ACHOLURIC JAUNDICE[1]

Synonym.—Chronic Splenomegalic Hæmolytic Jaundice.

Ætiology.—Acholuric jaundice is a familial disease, in which an hereditary abnormality of the red corpuscles is transmitted as a Mendelian dominant. It may occur in as many as four generations and may be transmitted through healthy parents. The abnormality presumably exists from birth, but the symptoms of the disease, though sometimes present from early infancy, may not manifest themselves till a much later age and may even remain in abeyance throughout life. It is often stated that there is a non-hereditary form of the disease, the so-called *acquired acholuric jaundice*, but it is probable that the familial nature of the condition could always be demonstrated if a sufficiently thorough investigation of the family were made.

Pathology.—The essential abnormality is an increase in the fragility of the red corpuscles, which leads to excessive hæmolysis with liberation of hæmoglobin and the formation of excess of bilirubin, so that jaundice develops and the patient may become anæmic. There are no abnormal hæmolysins in the blood, nor is there any evidence that the hæmolysis is dependent on over-activity of the spleen.

Symptoms.—The severity of the disease is extremely variable. There may be no symptoms at any time, the condition being recognised only on a routine examination of the blood. Most patients have a mild degree of jaundice, and give a history either that they have always been jaundiced, or that they have always been liable to attacks of jaundice. There is no pruritus. Irregularly recurring attacks or "crises," in which jaundice appears or in which an existing jaundice grows deeper, are characteristic of the disease. Such crises are usually mild, and apart from the jaundice the patient merely notices that he is slightly out of sorts. Occasionally they are more serious and are accompanied by the symptoms of an acutely developing severe anæmia; there is then often a high temperature with nausea and vomiting. Between the crises the jaundice and anæmia may be very slight or even disappear; but in some cases they persist, and the anæmia may be sufficient to interfere seriously with the patient's mode of life. It not infrefrequently happens that a crisis suddenly develops in an adult who gives no history of previous jaundice; in such cases the crises are particularly liable to be severe. Crises may follow over-exertion or infection.

Calcium bilirubinate gall-stones may develop as a result of the chronic bilirubinæmia. These may give rise to attacks of biliary colic, which may be accompanied by an increase in the jaundice, which is quite independent

[1] I am indebted to Dr. R. L. Waterfield, Clinical Pathologist to Guy's Hospital, for this article.—A. F. H.

of the hæmolytic crises. An unexplained complication is chronic ulceration of the legs, which may be the chief and sometimes the only symptom of the disease.

Splenomegaly is usually present; though occasionally extreme, it is commonly of moderate degree. The spleen may increase in size during a crisis, and may be painful and tender.

The fæces are normal in colour, and the urine, though dark as the result of the presence of urobilin, contains no bile.

In normal fully oxygenated blood the red corpuscles show no hæmolysis in a 0·50 per cent. solution and only slight hæmolysis in a 0·45 per cent. solution of sodium chloride. In acholuric jaundice the fully oxygenated corpuscles show gross hæmolysis in a 0·45 per cent. solution and lesser degrees of hæmolysis in stronger solutions, sometimes even as high as a 0·80 or 0·85 per cent. solution. The corpuscular diameter is usually diminished and often very markedly so, but occasionally it is normal or even above normal. But the corpuscles are disproportionately thick, so that the corpuscular volume and colour index instead of being diminished are normal or above normal; they may be higher than in any disease except pernicious anæmia. This discrepancy between corpuscular volume and colour index on the one hand and corpuscular diameter on the other occurs in no other disease and immediately distinguishes acholuric jaundice from pernicious anæmia. In stained films there is gross irregularity in the size of the corpuscles; the small ones tend to be deeply stained, while the large ones are feebly stained and often polychromatic. In shape they are of a remarkably uniform roundness, and stippled corpuscles are unusually scarce. Yet reticulocytes frequently constitute over 10 per cent. of the red corpuscles and are sometimes much more numerous. In severe crises large numbers of nucleated red corpuscles, mostly normoblasts, may appear. There is often a polymorphonuclear leucocytosis, which may reach 40,000 or more per c.mm., and among the cells there may be myelocytes and even myeloblasts. As the jaundice is hæmolytic the van den Bergh test gives only an indirect reaction. Occasionally, however, obstructive jaundice is present as well owing to the presence of a pigment stone in the common bile duct; a direct reaction is then present as well.

Diagnosis.—The diagnosis is suggested by the association of splenomegaly with long-standing jaundice or recurrent attacks of jaundice. It is strengthened by a history of jaundice in other members of the family. Its confirmation depends on finding increased fragility of the red corpuscles and the characteristic blood picture, particularly the discrepancy between the corpuscular volume and diameter and the increased fragility. The blood picture distinguishes the condition from other hæmolytic anæmias, from pernicious anæmia, chronic myelogenous leukæmia and splenic anæmia. Chronic ulceration of the legs should always call to mind the possibility that the underlying cause may be acholuric jaundice, even in the absence of jaundice and splenomegaly. Finally it must be remembered that attacks of biliary colic may occasionally be a complication of acholuric jaundice.

Prognosis.—If in the early stages the symptoms are mild they do not generally become more severe at a later period. Even severe crises generally end spontaneously. Very rarely the anæmia proves fatal, especially when severe crises occur in adults who give no previous history of the disease.

Treatment.—In mild or latent cases no special treatment is required, but patients should avoid undue exertion and treat with care any minor infection they may contract. When the anæmia or other symptoms are sufficient to interfere with the patient's activities splenectomy should be performed. At the same time the gall-bladder should be examined for calculi and any stones present removed, but there is no indication for cholecystectomy. In very severe crises transfusion may be necessary to prepare the patient for operation. The effects of splenectomy are dramatic: the jaundice and the anæmia quickly disappear and the leg ulceration heals. The increased fragility persists, though it may be slightly lessened. The disproportionate thickness of the corpuscles and the resulting discrepancy between the corpuscular volume and the diameter remain, but the reticulocytosis and leucocytosis, which are secondary to the anæmia, usually disappear.

CONGESTION OF THE LIVER

Ætiology.—When the outflow of blood from the hepatic vein is impeded as a result of right-sided heart failure, following primary disease of the heart or obstructive pulmonary disease, passive congestion of the liver may result. It is also produced by thrombosis of the hepatic veins, which is a rare condition generally secondary to some neighbouring malignant, syphilitic or inflammatory disease.

Pathology.—The sublobular and intralobular veins are dilated. The centre of each lobule thus appears as a dark spot, whilst the outer part is pale owing to fatty infiltration; the mottled appearance resembles the section of a nutmeg and has led to the name "nutmeg liver."

Symptoms.—In addition to the symptoms of the cardiac or pulmonary disease, which has led to the right-sided heart failure, special symptoms result from the passive congestion of the liver. The capsule of the liver is stretched and pain results, especially if the enlargement is rapid. When the increase in size is more gradual, there is a feeling of fullness and weight in the right hypochondrium. The liver can be felt to extend considerably lower than normal, its size varying from time to time according to the condition of the heart. It is firm and tender, especially if the congestion is recent and acute. Distinct expansile pulsation can sometimes be felt by placing one hand in the loin and the other just below the right costal margin; this corresponds with ventricular systole if tricuspid regurgitation exists and with auricular systole if there is tricuspid stenosis. It must be distinguished from the non-expansile pulsation transmitted through the diaphragm from the hypertrophied and labouring right ventricle.

The congestion of the liver leads in turn to congestion of the organs which are drained by the portal vein. Anorexia, discomfort immediately after food, flatulent distension of both stomach and intestines from deficient absorption of the gas swallowed with the food or produced by fermentation, and constipation are commonly present. The combination of slight jaundice with cyanosis produces a characteristic dusky green colour of the face. The jaundice, is, however, often latent, a positive indirect but negative direct van den Bergh reaction being obtained.

Ascites is common, but is rare in the absence of general œdema, being

mainly due to the same causes; it is also in part a direct result of portal congestion and sometimes of chronic peritonitis. The spleen is very rarely enlarged in spite of the interference with the outflow of blood in the splenic vein by the hepatic congestion.

Diagnosis.—When the heart disease is obvious, the diagnosis is easy. Sometimes, however, the most prominent symptoms are due to the congestion of the liver, and the diagnosis from cirrhosis may be difficult. In congestion of the liver the spleen is not enlarged, and the symptoms rapidly improve and the liver diminishes in size with rest and cardiac tonics; moreover, hæmatemesis, though common in cirrhosis, very rarely occurs in passive congestion in spite of the congestion of the gastric mucous membrane.

A history of alcoholism does not necessarily point to cirrhosis; if the heart is failing and there is no valvular disease, the enlargement of the liver is probably due to congestion and the heart failure in part to alcoholic poisoning. The diagnosis would be confirmed if the ankle-jerks are lost, as latent neuritis is frequently associated with an alcoholic heart and congested liver, but rarely with cirrhosis.

Treatment.—Apart from the treatment of the primary condition the local pain and discomfort are rapidly relieved by the application of six leeches over the hepatic region. Mild purgation with Epsom salts also helps to relieve the portal congestion.

GLYCOGEN DISEASE (VON GIERKE'S DISEASE)[1]

This rare disease, first described by Von Gierke in 1929, is characterised by an abnormal deposition of glycogen in the tissues, the liver being the organ principally affected.

Ætiology.—Glycogen disease occurs in both sexes. It is congenital and may be familial. The relatively high incidence of cousin-marriages amongst the parents of affected patients suggests that the condition may possibly be inherited as a Mendelian recessive character.

Pathology.—Deposition of glycogen in the liver, kidney, heart and other organs gives rise to distension of the individual cells and gross enlargement of the affected organs. The blood glycogen content (principally the glycogen contained in the red cells) is also raised. Whereas glycogen normally disappears from the tissues rapidly after death, in glycogen disease it is peculiarly stable. Possibly this is due to an abnormal linkage with protein, but more probably to a congenital deficiency of a factor acting between the glycogen and the glycogen-splitting ferment. Pituitary dysfunction has been suggested as the underlying cause. The glycogen of the tissues can only be mobilised with difficulty during life, with the result that the fasting blood sugar is low and acetonuria occurs. This delayed mobilisation is demonstrated by the adrenaline test, the normal rise of blood sugar following the injection of adrenaline being absent or delayed. That there is usually some delay in glycogen storage also is shown by an abnormal glucose tolerance test. The blood cholesterol is raised.

[1] I am indebted to Dr. R. W. B. Ellis, Assistant Physician to the Department for Children's Diseases, Guy's Hospital, for this article on Glycogen Disease.—A. F. H.

Symptoms.—The most striking symptom is lack of growth and development, the older patients often showing well-marked infantilism. The large size of the liver causes abdominal distension, but seldom any discomfort. Obesity of local or generalised distribution has been described. Occasionally convulsions occur, which are probably attributable to the hypoglycæmia, but may be associated with local depositions of glycogen in the brain. Whilst some of the patients are of low vitality with poor resistance to infection, others suffer very little disturbance of normal health and activity. In a few instances the condition appears to have undergone spontaneous cure. Involvement of the heart (cardiomegalia glycogenica) may result in sudden death.

Diagnosis.—The presence of a large, smooth, non-tender liver, in the absence of splenic enlargement, jaundice or other evidence of cirrhosis, will suggest the diagnosis, which is confirmed by the low fasting blood sugar, acetonuria and abnormal response to the adrenaline test.

Treatment.—There is at present no method known by which glycogen mobilisation can be restored to normal in this disease. If hypoglycæmic symptoms occur, the diet should be relatively high in carbohydrates. Injections of combined anterior pituitary hormones have been tried, but the results have been disappointing.

INFECTIONS OF THE LIVER

Infection may be conveyed to the liver by (1) the hepatic artery, (2) the portal vein, and (3) the bile ducts.

(1) *Systemic blood infections.*—Hepatitis forms part of the clinical picture of yellow fever and spirochætosis ictero-hæmorrhagica. Infective hepatitis may also occur in malaria, in typhoid and paratyphoid fever and similar, but non-specific infections, and very rarely in influenza, streptococcal septicæmia, especially in association with erysipelas, and in lobar pneumonia. Acute hepatitis of infective origin may occur sporadically and give rise to both small and extensive epidemics (p. 694).

(2) *Portal infections.*—Acute, subacute and chronic amœbic hepatitis (p. 709) and suppurative pylephlebitis (p. 721) result from infection conveyed by the portal vein.

(3) *Ascending cholangitis.*—Hepatitis may be caused by infection ascending the bile ducts when stasis is produced by obstruction to the common bile duct. Very acute cases, especially when associated with gall-stones, may result in suppurative cholangitis with formation of innumerable minute abscesses in the liver. In chronic cases perilobular (or " biliary ") cirrhosis is the final result (p. 698).

CATARRHAL JAUNDICE

Two separate conditions are commonly described as catarrhal jaundice, both of which may occur in sporadic and epidemic form. The term is correctly applied only to the first; the second is more accurately called acute hepatitis (p. 698).

Ætiology and Pathology.—Catarrhal jaundice is more common in children and young adults than in older people. Single cases are quite common, but groups may occur in houses, institutions and villages, but large epidemics, such as that which developed in the autumn of 1915 in Gallipoli, are rare.

The majority of cases diagnosed in England as catarrhal jaundice are probably correctly labelled and depend upon obstruction to the flow of bile secondary to acute gastro-duodenal catarrh. The obstruction may be caused in various ways. (1) The swelling of the mucous membrane of the duodenum may itself be sufficient to obstruct the mouth of the common bile-duct. (2) The duodenitis is probably often associated with an ascending cholangitis; the swollen mucous membrane of the mouth of the duct where it is surrounded by Oddi's sphincter must increase the obstruction. (3) In most of the recorded autopsies the mouth of the common bile-duct was found to be obstructed by a plug of mucus and epithelial debris. (4) The inflammation of the duodenum and terminal part of the common bile-duct would be likely to cause achalasia and in more severe cases spasm of Oddi's sphincter and so add a functional element to the organic obstruction already present.

Catarrhal jaundice is so rarely fatal that the number of recorded autopsies is very small. The following *post-mortem* report from the case of a girl of 19, who died from an accidental injury at the height of an attack, is typical of the small number on record. The mucous membrane of the stomach and duodenum was swollen and showed submucous ecchymoses, and the papilla of Vater was unusually prominent; there was no bile pigment in the duodenal contents, but the common bile-duct, hepatic ducts and gall-bladder were moderately dilated and contained dark, sticky bile; the mouth of the common bile-duct was completely obstructed as a result of inflammatory swelling of its wall with overgrowth of lymphoid tissue, and no bile passed into the duodenum on compressing the gall-bladder; the liver and pancreas were macroscopically and microscopically normal (Eppinger).

The liver is affected only in the comparatively rare cases, in which the jaundice persists for a considerable period, when the usual degenerative changes which follow obstruction to the flow of bile gradually develop.

Symptoms.—The clinical picture of true catarrhal jaundice shows remarkably few variations, and is exactly what might be expected with the pathogenesis just described. The initial symptoms are those of acute gastritis. The patient complains of epigastric discomfort, which rarely amounts to pain, with anorexia and nausea. Pressure in the epigastrium produces acute discomfort. If the patient attempts to eat he is generally sick. Diarrhœa may occur. He feels ill and his temperature is raised. In two or three days improvement sets in, but just when he thinks he has almost recovered his urine becomes dark, his stools pale, and his conjunctivæ and subsequently his skin becomes jaundiced. His temperature falls, and by the time the jaundice has fully developed he feels perfectly well, except that he is still likely to be nauseated or to vomit if he eats fatty food, especially if he does not remain in bed. At this stage examination shows that the epigastric tenderness had disappeared, but that the liver is a little enlarged and slightly tender. The gall-bladder may be palpable—an important sign that the jaundice is obstructive and not of hepatic origin, and in severe cases the spleen is slightly enlarged. The jaundice generally begins to fade

within a week, and by the end of a fortnight all symptoms and signs have disappeared. In epidemics mild cases occur in which no jaundice follows the initial symptoms caused by the acute gastro-duodenitis.

In the majority of cases the lævulose test shows no hepatic insufficiency. When, however, recovery is delayed, secondary hepatic degeneration occurs and the lævulose test may show a moderate degree of insufficiency. In the early stages the material obtained through a duodenal tube contains excess of mucus and cells, but no flow of bile follows the injection of magnesium sulphate. As the jaundice decreases bile is obtained, and for a short time it contains leucocytes, epithelial cells and pigment granules.

Diagnosis.—When jaundice, unaccompanied by pain and with very slight constitutional symptoms, develops in a patient with mild gastric symptoms of a few days' duration, catarrhal jaundice is the probable diagnosis. When the symptoms do not abate with the onset of jaundice and much constitutional disturbance is present, especially if the spleen is enlarged, the possibility of acute infective hepatitis, including spirochætosis ictero-hæmorrhagica, requires consideration. When the initial gastric symptoms are absent and the jaundice persists for more than a fortnight, catarrhal jaundice can be excluded. When pain of any severity occurs, especially after the onset of jaundice, and when the gall-bladder is tender, fever persists or the jaundice recurs, gall-stones are probably present.

Treatment.—The patient should be kept in bed on a plain diet containing as little fat as possible, and his bowels should be opened daily with Epsom salts, which at the same time promote biliary drainage. He should not be allowed to get up until the jaundice is beginning to disappear.

ACUTE AND SUBACUTE HEPATIC NECROSIS

Ætiology.—Hepatic necrosis may be caused by a large variety of intrinsic and extrinsic toxins, of which the following are the most important.

(*a*) *Intrinsic toxins.*—i. An unknown toxin which may develop in the later months of pregnancy, causing the toxic jaundice of pregnancy.

ii. An unknown intrinsic toxin is probably the cause of the rare cases of acute necrosis in which no extrinsic cause can be found.

(*b*) *Extrinsic toxins.*—i. Acute alcoholic poisoning.

ii. Delayed chloroform poisoning. This is probably the cause of most cases of death a few days after childbirth in the absence of sepsis, but an overdose during prolonged labour is much less common than it was twenty-five years ago. I know two anæsthetists who developed a mild form of toxic jaundice as a result of inhaling chloroform in small doses day after day.

iii. Delayed bromethol (avertin) poisoning. Bromethol is dangerous only if the liver is already damaged. I know of several cases in which death occurred a few days after an operation on a jaundiced patient from what was described as "shock," but which was, I believe, really the result of delayed avertin poisoning.

iv. Carbon tetrachloride used in treatment of ancylostomiasis.

v. Trinitrotoluene and tetrachlorethane, which caused an epidemic of jaundice in munition and aeroplane workers respectively during the War of 1914–1918 (pp. 385 and 389).

ACUTE INFECTIVE HEPATITIS

Widespread epidemics of a non-spirochætal acute hepatitis occurred in Sweden in 1926 and 1927, and small epidemics of a mild character are common in Great Britain, where they are generally confused with true catarrhal jaundice. The condition is infective and probably caused by a virus, which is transmissible from man to swine and swine to swine.

It is clinically indistinguishable from the infective hepatitis which is a very rare complication of typhoid and paratyphoid fever and of influenza ; in the former it generally appears about the third week and in the latter towards the end of the first week.

Symptoms and Diagnosis.—In most cases there are no pre-icteric symptoms of any kind, in contrast with the indigestion which constantly precedes the onset of catarrhal jaundice. The patient first notices that his urine is becoming dark, then that his stools are pale, and finally that he is jaundiced. The onset of jaundice is accompanied by symptoms of general toxæmia—anorexia, headache and weakness, and occasionally vomiting and diarrhœa. The temperature is generally slightly raised. There is no epigastric tenderness, but the liver is tender and slightly enlarged, and the spleen is often palpable. The jaundice is generally less deep than in catarrhal jaundice, and bile is always present in the stools. The jaundice lasts anything between a week and 2 or 3 months, the average duration being greater than in true catarrhal jaundice. Instead of the rapid complete recovery which is characteristic of the latter, convalescence is often prolonged and the patient may become very weak and emaciated. In rare cases the jaundice persists and the patient becomes increasingly toxic, dying eventually with all the symptoms of acute hepatic necrosis.

From the onset the lævulose test shows the presence of well-marked hepatic insufficiency. This is occasionally present many years after clinically complete recovery, whereas true catarrhal jaundice leaves the liver quite undamaged.

When the infective jaundice is secondary to some acute infection the primary illness runs its usual course, but instead of a normal convalescence after the former subsides, the above symptoms develop. The temperature is generally normal and the illness is mild in type, but the jaundice may last for several weeks. Symptoms of hepatic insufficiency rarely develop and complete recovery is the rule.

CIRRHOSIS OF THE LIVER

Cirrhosis of the liver is a condition in which the liver hardens as a result of the development of new fibrous tissue. Three entirely distinct forms occur.

(1) *Pericellular cirrhosis.*—This is invariably the result of congenital syphilis (p. 712).

(2) *Perilobular cirrhosis.*—This is the late result of the chronic hepatitis caused by ascending infection of the bile ducts (cholangitis), and is therefore also known as *biliary cirrhosis.* It is always associated with jaundice. It is

generally the result of infection following chronic obstruction of the common bile duct by a gall-stone, cicatricial stenosis (resulting from an injury during cholecystectomy), chronic pancreatitis, or carcinoma of the head of the pancreas, the common bile duct or ampulla of Vater. Cellular infiltration and new fibrous tissue form around the bile ducts and between the lobules of the liver with the final production of perilobular cirrhosis.

In these conditions the enlargement and hardness of the liver and the jaundice, which are primarily the result of retention of bile in the intra-hepatic ducts caused by obstruction to their outflow into the duodenum, may also be caused by the secondary perilobular cirrhosis. Consequently, if the obstruction is eventually relieved, the liver remains hard and large and the jaundice does not disappear. A measure of the degenerative changes in the liver can be obtained from the lævulose test, which shows no hepatic insufficiency at the onset of obstruction but a slowly increasing insufficiency if the obstruction is not overcome. In the more acute cases changes similar to those of subacute hepatic necrosis occur and death may ensue from hepatic failure.

A condition has been described as Hanot's biliary cirrhosis, which is said to affect children and young adults, often several members of a family, and to be characterised by enlargement of the liver and spleen, with chronic jaundice and febrile attacks, but rarely ascites. I have never seen a case which answered to this description, and I am exceedingly doubtful whether such a clinical entity exists. Even in France, where it was first described, it is now said to be exceedingly rare. The term has probably been used to include the biliary cirrhosis described above and also cases of splenic anæmia with cirrhosis and of acholuric jaundice.

ALCOHOLIC HEPATITIS

A. Pre-Cirrhotic Alcoholic Hepatitis

Definition.—In the early stages of chronic alcoholic poisoning of the liver complete or almost complete recovery may take place if the patient becomes teetotal. Not only do the symptoms disappear, but the liver becomes smaller and softer, and the lævulose test, which originally showed gross hepatic insufficiency, shows little or no abnormality and a positive van den Bergh reaction may become negative. Though there is no pathological evidence as to the exact condition of the liver before and after treatment, it is clear that actual cirrhosis cannot have taken place. It is therefore reasonable to regard the condition as pre-cirrhotic and to call it alcoholic hepatitis.

Ætiology.—Whereas the fully developed picture of cirrhosis of the liver has become rare since the War of 1914–1918, alcoholic hepatitis has become increasingly common, especially among the well-to-do. Whilst the poor man's beer is more expensive and weaker than it was before 1914, many people celebrate their newly acquired wealth by excessive indulgence in cocktails, champagne and whisky. Some have been drinking in obvious excess, though they may never get drunk, but with others it is the concentration of the alcohol and the fact that it is drunk when the stomach is empty rather than the total quantity consumed which are mainly responsible for

the damage done to the liver. Consequently alcoholic hepatitis is not at all uncommon among young adults of both sexes, though fully developed cirrhosis is now, as it has always been, rare before middle age. In older patients a sedentary life is an important predisposing factor.

The condition has long been recognised as common among Europeans living in tropical countries, where the consumption of highly spiced food and repeated attacks of malaria, together sometimes with amœbiasis and enteric fever, are additional factors.

Symptoms.—A feeling of discomfort, rarely amounting to actual pain, is felt in the region of the liver. Symptoms of alcoholic gastritis, especially morning anorexia and nausea, are often present with hypochlorhydria or achlorhydria and excess of mucus in every fraction of a test-meal. The patient's complexion is sallow, and there is sometimes a slight degree of jaundice. The liver is hard, moderately enlarged and tender, and the spleen may be just palpable. The patient says he is "liverish"; he is irritable and depressed, and complains of a feeling of general unfitness, headache and drowsiness. Intestinal flatulence may occur as a result of deficient absorption of gas secondary to slight portal obstruction, which may also cause occult blood to appear in the stools, though actual hæmatemesis and melæna are rare.

Periods of comparative well-being may alternate with acute exacerbations or "liver attacks," which are generally caused by increased alcoholic excess and to a less extent by over-eating, and sometimes by exposure to cold. During such an attack the liver becomes larger and more tender, and the stretching of the capsule may cause acute pain. In rare cases hæmatemesis occurs. With suitable treatment an attack generally subsides within a fortnight, and even in severe cases a month or six weeks is generally sufficient to restore the patient to good health. If he becomes teetotal complete recovery may occur; otherwise cirrhosis will eventually develop.

Ascites never occurs in the pre-cirrhotic stage.

Treatment.—The patient should be kept in bed on a diet of citrated milk until all the symptoms have disappeared and the liver is no longer tender. If gastritis is present, the stomach should be washed out every morning (p. 586). The diet can then be gradually increased, but the patient should continue on the diet described on p. 706 for several months. It is essential that he should become completely teetotal and should remain so for the rest of his life. It should be pointed out to him that his liver has become abnormally vulnerable, and that even a small quantity of alcohol is a poison for him. He should be warned of the danger of cirrhosis if he does not follow the advice given him. It is remarkable how easily the majority of such patients can become teetotal; fortunately they have none of the craving for alcohol experienced by dipsomaniacs, but only take it because they like it or for the sake of conviviality.

B. Cirrhosis of the Liver

Synonyms.—Portal or Multilobular Cirrhosis; Laennec's Cirrhosis.

Definition.—The portal or multilobular form of cirrhosis of the liver is so much the most common that it is generally described shortly as cirrhosis of the liver. It is a disease in which degeneration of the hepatic cells occurs

in association with fibrosis spreading from the portal spaces to enclose various numbers of lobules.

Ætiology.—Cirrhosis of the liver is generally fatal about the age of fifty, but a distinct group of cases occurs in childhood. It is three times more common in men than in women, but only slightly more so in boys than in girls. Cirrhosis is in very rare instances familial, presumably as a result of an inborn defect of the liver cells which renders them abnormally vulnerable to toxins and liable to premature degeneration; this may then be associated with chronic lenticular degeneration (Wilson's disease). It is more common in individuals who follow a sedentary occupation than in those who lead an active life, and among the poor than the well-to-do, though since the War of 1914–1918 it has become less common among the former and more common among the latter.

A very large majority of patients with cirrhosis of the liver have indulged excessively in alcohol; it is three times more common among people connected with the liquor trade than among the general public. Any condition, such as syphilis, amœbiasis and malaria, which can damage the liver predisposes to the development of alcoholic cirrhosis. Cases occur, however, especially in India, Egypt, and Dutch East Indies, and in children, in which alcoholic excess can be excluded with certainty. Thus cirrhosis is not infrequent among Brahmins, the majority of whom indulge in large quantities of ginger, cardamoms, red pepper and other spices, but never touch alcohol. I have seen a typical case with severe ascites in a lady of thirty, who was teetotal, had never suffered from malaria, and had always taken an ordinary diet. The multilobular cirrhosis which develops as a complication of splenic anæmia as the result of the action of a poison produced in the spleen is almost indistinguishable pathologically from that associated with chronic alcoholism.

Pathology.—Cirrhosis very rarely develops experimentally in animals as a result of chronic alcoholic poisoning, although fatty changes and occasionally necrosis with a slight degree of small-celled infiltration may be produced. It occurs in less than 3 per cent. of drunkards dying from the effect of alcoholism, and its geographical distribution does not correspond with that of chronic alcoholism, cirrhosis being rare, for example, in Scotland and Ireland; and when excessive indulgence in alcohol leads to nervous or cardiac symptoms, cirrhosis of the liver is rare. It is probable, therefore, that alcohol produces cirrhosis of the liver indirectly by leading to gastro-enteritis; the poisons produced in the alimentary canal are absorbed and pass to the liver. As ordinary gastro-enteritis does not lead to cirrhosis, an additional factor must be present. This is probably the direct poisonous action of alcohol and occasionally of other toxins, such as that of malaria, on the liver cells, which thus become more liable to injury by gastro-intestinal toxæmia.

Cirrhosis of the liver may result from the action of poisons which reach it from the spleen. This is the cause of the cirrhosis of splenic anæmia, as the liver does not become affected if the spleen is removed at a sufficiently early stage. In a typical early case under my care a fragment of liver removed when splenectomy was performed showed no pathological changes.

It is probable that the poisons which cause cirrhosis of the liver lead both to degeneration of the hepatic cells and to irritative hyperplasia of the connective tissue; the degeneration of the hepatic cells is increased by the

connective-tissue hyperplasia, which in turn is exaggerated by replacement fibrosis following atrophy of the hepatic cells.

The size of the liver varies greatly; it may be much smaller or much larger than normal. The large liver is due to compensatory hyperplasia of the liver cells and to a less extent to fatty degeneration.

The surface of the liver is irregular. The projections may be as small as those of a granular kidney, but more frequently they give rise to a hob-nailed appearance.

The obstruction to the intrahepatic branches of the portal vein produces a rise in pressure in its tributaries; this results in dilatation of the collateral circulation which normally exists between the portal and general venous systems. This compensatory circulation is carried out by the following groups of vessels.

1. An anastomosis may develop within the liver between the branches of the portal vein and the intralobular veins. Large branches pass from the liver and its capsule to the phrenic and intercostal veins, where the liver and diaphragm are uncovered by peritoneum. Occasionally a single large vein passes from the liver in the falciform ligament by the side of the obliterated umbilical vein to join the veins of the abdominal wall at the umbilicus; the subcutaneous veins around and above the umbilicus are consequently dilated, and a large bunch of dilated veins may form at the umbilicus.

2. The gastric veins anastomose with the œsophageal veins, which open into the azygos veins; the veins in the lower end of the œsophagus may become greatly dilated.

3. The inferior mesenteric vein communicates through the superior and middle hæmorrhoidal veins with the inferior hæmorrhoidal vein, which is a branch of the internal iliac vein; this might be expected to give rise to hæmorrhoids, but they are hardly more common among patients with cirrhosis than in individuals with healthy livers.

4. The veins of Retzius unite the radicles of the portal veins in the intestines and peritoneum with the inferior vena cava and its branches. These include the retro-peritoneal veins, which are often greatly enlarged, especially in the neighbourhood of the kidneys.

Symptoms.—About 50 per cent. of patients with cirrhosis of the liver die from some intercurrent disease or accident. Such cases are generally described as latent; but in the majority symptoms due to the condition were probably present before death, and the fatal result of the intercurrent disease or accident was often due to the diminished power of resistance to toxæmia which results from cirrhosis. In some cases, however, the disease may be genuinely latent, owing to compensatory hyperplasia of the liver cells and to the development of an efficient collateral circulation between branches of the portal vein and systemic veins.

In a large majority of cases the symptoms caused by cirrhosis are preceded by those of pre-cirrhotic hepatitis, which have already been described (p. 700), and alcoholic œsophagitis and gastritis have generally been present for many years. The patient habitually wakes in the morning with a feeling of nausea and no desire for breakfast; violent retching often occurs, and he then vomits a small quantity of alkaline watery fluid, after which some bile-stained mucus may appear. A sense of uncomfortable fullness is also felt in the epigastrium after other meals, and the nausea and vomiting may recur. The

appetite is poor, and there is a special repugnance for meat. When cirrhosis develops, the symptoms due to catarrh are exaggerated by the congestion of the gastric and intestinal mucous membrane caused by portal obstruction; this leads to the secretion of still more mucus, and by preventing absorption of gas leads to flatulence, which aggravates the feeling of distension already present. Flatulence is a constant early symptom and is the earliest sign of portal congestion; it is " le vent avant la pluie."

The complexion is generally sallow and bloated with dilated capillary or arterial angiomata, especially over the nose and cheeks. In the later stages the face is drawn, the cheeks and eyes are sunken, and the conjunctivæ are congested and often slightly tinged with bile. The skin of the body is dry and inelastic; numerous spider angiomata appear on the face, neck and back as the disease progresses, and red or purple areas of skin may be produced by the uniform distension of small venules. Purpura and various forms of erythema may occur.

The tongue is flabby and furred, the gums readily bleed, and pharyngitis is common owing to chronic irritation by alcohol. The breath is often offensive as a result of oral sepsis.

The patient is generally constipated, but attacks of diarrhœa may occur, especially during the last few weeks of life.

In a large proportion of cases the liver is enlarged. Its lower border can generally be felt below the costal margin in the right nipple line; but ascites and occasionally flatulent distension of the intestines or obesity may render it impalpable. It is always very hard; its edge can consequently often be felt even when it is not enlarged. In rare cases an enlarged liver can be observed to shrink as the disease progresses until it ceases to be palpable, and after death it may be found to be considerably smaller than normal. The irregular surface of the liver can occasionally be recognised by palpation, The liver is insensitive in contrast with its tenderness in pre-cirrhotic alcoholic hepatitis.

Discomfort is often felt in the right hypochondrium, but pain only occurs if the disease is complicated by an attack of perihepatitis.

In about 35 per cent. of cases jaundice occurs. It is generally slight and is often transient. In the absence of jaundice van den Bergh's test may give a positive indirect reaction with a delayed or biphasic direct reaction.

In 80 per cent. of cases the spleen is enlarged. Owing to its hardness it is easily felt unless it is obscured by ascites or intestinal flatulence. Discomfort or pain may result from stretching of the capsule if rapid enlargement occurs; more frequently it is due to perisplenitis. When both the liver and spleen are much enlarged, the left lobe of the former may overlap the latter.

Hæmatemesis occurs in about 25 per cent. of cases. It is generally an early symptom, and is often the first indication of the presence of serious disease, though it is generally preceded by symptoms of gastritis. It is uncommon after ascites has developed. The hæmatemesis generally takes the form of a single large hæmorrhage; but sometimes a smaller quantity is vomited during the next few days. It is generally repeated only after a considerable interval. The blood collects slowly in the stomach and often passes into the intestine, causing melæna without hæmatemesis. When a considerable quantity has collected in the stomach, the distension causes it to be vomited; small quantities are not brought up unless vomiting occurs

from some independent cause. The blood collects more slowly than in gastric ulcer and is therefore generally more clotted and darker, as there is more time for digestion to occur; for the same reason fainting occurs less frequently. Death from hæmatemesis is very unusual in cirrhosis and accounts for less than 5 per cent. of the mortality.

In the majority of cases the hæmorrhage is a result of rupture of varicose œsophageal veins in the lowest 3 inches of the œsophagus, when they can be easily demonstrated with the X-rays. The blood runs into the stomach, though in severe cases it may well up directly from the œsophagus. Hæmorrhage may also occur from minute erosions secondary to acute gastritis, sometimes associated with varicose veins. The erosions are very difficult to discover *post mortem*, and possibly in some cases there is no actual loss of surface, the hæmorrhage corresponding with the bleeding which occurs from other mucous membranes as a result of the toxæmia. In very rare cases melæna may result from thrombosis of the portal vein or one of its branches (*vide* p. 721).

Epistaxis is common. The hæmorrhage generally comes from a point on the anterior part of the septum. In the late stages oozing from the nose may occur, as well as from the gums, lungs, kidneys and uterus, as a result of the toxæmia caused by hepatic insufficiency, and small hæmorrhages often occur under the skin. Hæmoptysis, however, is generally due to the cirrhosis being associated with pulmonary tuberculosis.

Ascites is present in most cases of cirrhosis which run their full course; it is a late symptom in uncomplicated cases, and is often absent if the patient dies from some independent cause or from hæmatemesis at a comparatively early stage. The onset is generally gradual, but it occasionally develops suddenly after a blow on the abdomen, a chill or an acute infection; it is also acute in portal thrombosis. It sometimes disappears spontaneously shortly before death. It is a result of portal congestion, as the intrahepatic branches of the portal vein are compressed, some being completely obliterated; occasionally others are thrombosed, and in rare cases thrombosis of the portal vein itself occurs. This is not the sole cause of ascites, as the fluid may collect with extreme rapidity instead of *pari passu* with the changes in the liver, and it is often absent when the portal pressure is high as shown by the occurrence of hæmatemesis. In many cases it is secondary to chronic peritonitis.

The ascitic fluid is clear and sometimes slightly bile-stained. Its reaction is alkaline, its specific gravity between 1008 and 1015, and a large proportion of the cells it contains are endothelial. When the ascites is due to chronic peritonitis the specific gravity is greater than 1015, more albumin is present, flakes of fibrin may form on standing and polymorphonuclear cells are found. When 50 per cent. or more of the cells are lymphocytes, tuberculous peritonitis is probably present. In rare cases the ascites is chylous or chyliform; still more rarely it is hæmorrhagic.

Œdema of the ankles is frequent, but it is rarely very marked, though occasionally it speads up the legs to the abdomen and back. It often develops before or at the same time as the ascites, in which case it must be toxic in origin, but most frequently it follows it and is caused by pressure of the ascitic fluid on the inferior vena cava and the abdominal lymphatics; it rapidly diminishes when the abdomen is tapped.

Muscular weakness and loss of energy may be the earliest symptoms; they are constant in the late stages. The muscles are flabby and atrophied, and marked wasting of the whole body occurs.

The rise in intra-abdominal tension caused by flatulent dyspepsia and later by ascites is frequently followed by the development of hernias.

The urine is diminished in quantity and the specific gravity is high. It is very acid and high coloured, and a large deposit of urates generally forms on standing. It contains excess of urobilin, but even when slight jaundice is present bile-pigment is often absent. In the late stages the percentage of nitrogen excreted as ammonia increases at the expense of urea; this is due to ammonia being required to unite with the excess of organic acids present, and not to inability of the liver to form urea, as ammonia given by the mouth is still excreted as urea. In the last days of life leucin and tyrosin are sometimes found.

Albuminuria is occasionally present as a result of the hepatic toxæmia, nephritis, or congestion of the kidneys from heart failure. Glycosuria is rare, as the glycogenic function of the liver is maintained to a certain extent even in advanced cases, but the lævulose test for hepatic efficiency generally shows considerably impairment throughout the course of the disease, though owing to compensating hyperplasia this is often less than might be expected.

The blood is generally normal, except when severe hæmorrhages have led to secondary anæmia. I have seen two cases in which the achlorhydric gastritis caused by chronic irritation of the stomach by alcohol led to the development of typical pernicious anæmia in patients with cirrhosis.

The temperature is often raised in rapidly progressing cases apart from complications such as tuberculosis and infective endocarditis.

In the late stages of cirrhosis the toxæmia which results from hepatic insufficiency gives rise to restlessness, irritability, muttering delirium, and finally to coma.

Nervous symptoms may also be present as a direct result of chronic alcoholism. Delirium tremens may follow a drinking bout and occasionally hæmatemesis; slight mental disturbance and muscular tremor are not uncommon, but neuritis is a rare complication.

Active tuberculous disease is found more frequently in patients dying with cirrhosis of the liver than with other diseases. This is probably due to the diminished resistance to tuberculous infection caused by chronic alcoholism. The lungs are most often affected, phthisis being the cause of death in 15 per cent. of cases of cirrhosis, and tuberculous pleurisy is not uncommon. Either the cirrhosis or the phthisis may be completely latent and remain undiscovered until death.

Tuberculous peritonitis is found in 10 per cent. of cases; the accompanying ascites is often thought during life to be due to the cirrhosis. The lungs are generally also involved. The majority of cases of tuberculous peritonitis in adult males are associated with cirrhosis.

Diagnosis.—A regularly enlarged, hard liver in an alcoholic individual is generally the result of cirrhosis. The occurrence of hæmatemesis, enlargement of the spleen, slight jaundice or a positive indirect van den Bergh reaction, makes the diagnosis still more probable. The enlarged hard liver, which is produced by chronic venous congestion in heart failure, may be difficult to distinguish from cirrhosis if the patient is seen when the heart is no

longer failing. A history of heart failure with pain in the hepatic region and any evidence of existing heart disease point to congestion.

The diagnosis from syphilis and from malignant disease of the liver is discussed elsewhere (p. 714 and p. 719).

Splenic anæmia with hæmatemesis can be distinguished from cirrhosis by the much greater enlargement of the spleen and the presence of leucopenia. It must, however, be remembered that cirrhosis of the liver always develops sooner or later in untreated splenic anæmia.

The symptoms in the last stages are often indistinguishable from those of uræmia, and the diagnosis may be very difficult in the absence of a full history. But a much increased blood urea with high blood pressure, albuminuric retinitis or the presence of a large quantity of albumin with casts in the urine would prove that uræmia is present.

Prognosis.—If an individual with cirrhosis permanently gives up alcohol in the pre-ascitic stage, there is a good chance that the disease will not progress and that his symptoms will disappear. Even the damage done to the liver can be repaired to some extent by hyperplasia of its cells, a large liver being therefore a favourable sign, and the danger of hæmatemesis, together with the other ill-effects of portal congestion, may be overcome by a sufficient development of the anastomoses between the portal and general venous systems.

Much, therefore, depends upon the patient's character, as, if he is unable to control his desire for alcohol, the disease is certain to advance to a fatal issue. The younger the patient the more chance there is for functional compensation to occur, but the prognosis is always bad in children. However completely latent the disease may become, much of the damage to the liver is of course permanent, and the patient's power of resisting acute infections and all other diseases is materially reduced.

Fever is a serious symptom, as it indicates rapid advance of the disease or the presence of some complication. When the patient becomes drowsy death is almost certain to follow rapidly, but I have seen complete restoration to health occur in a semi-comatose, tremulous, apparently moribund man, who had drunk champagne in great excess for many years but remained completely teetotal after recovery from the acute illness.

In rare cases the disease runs a subacute course, death occurring within a few months of the onset of symptoms. Such cases are most frequent in comparatively young adults who are heavy drinkers. The liver is painful and tender, fever is present, emaciation is rapid, and multiple hæmorrhages are likely to occur. Such cases, however, are really examples of subacute necrosis of the liver.

Treatment.—Alcohol must be absolutely prohibited for the rest of the patient's life, and no medicine containing alcohol should be prescribed. Curries, pickles, ginger, all highly-seasoned food, vinegar, mustard, pepper, high game and ripe cheese must be permanently avoided.

Apart from these restrictions the diet in the early stages should be that required for the treatment of the associated chronic gastritis. In the late stage, when symptoms of hepatic insufficiency are present, the diet should consist entirely of milk, milk foods, vegetable purées and fruit, and even when improvement occurs very little animal food should be allowed. Half a pound of dextrose in a pint of lemonade should be given daily.

The bowels should be kept regular by means of Epsom salts. No other drugs are required in uncomplicated cases. The treatment of the gastritis, ascites and hæmatemesis is considered elsewhere. Recurrent severe hæmorrhage can sometimes be controlled by ligature of the coronary veins just below the diaphragm or by direct injection of varicose œsophageal veins with sclerosing fluid through an œsophagoscope.

The regular life led at a spa, such as Harrogate, combined with the use of a mild aperient water, is often very beneficial

The treatment of the drowsy toxæmic condition of the late stage is the same as that of subacute hepatic necrosis (p. 697).

HÆMOCHROMATOSIS

Synonyms.—Pigmentary Cirrhosis ; Bronzed Diabetes.

Ætiology and Pathology.—Hæmochromatosis is a very rare disease, in which large quantities of hæmosiderin, an iron-containing pigment, are deposited in various parts of the body, especially the liver, upper abdominal lymph glands, pancreas, suprarenal glands and skin, but very little in the kidneys and spleen. The deposition of pigment is associated with ordinary multilobular cirrhosis of the liver and cirrhosis of the pancreas, and the latter, by involving the islands of Langerhans, may give rise to diabetes mellitus. It occurs in about 7 per cent. of cases of cirrhosis of the liver in males and hardly ever in females. There is no excessive hæmolysis ; the quantity of iron deposited is much greater than in hæmolytic anæmias, in which the excess of iron is chiefly in the liver and kidneys, whereas in hæmochromatosis it is chiefly in the liver, pancreas and abdominal glands, to which it passes from the liver and pancreas.

The disease is extremely chronic. In advanced cases 30 grm. of iron may be deposited in the body compared with the normal of 0·3 grm. ; as the ordinary daily intake of iron in the food is about 10 mgrms. it would take 3000 days to accumulate, even if no iron were ever excreted. There must clearly be a failure in the elimination of iron, but it is unknown whether this is primary or the result of excessive deposition. Possibly the liver cells are affected by an unknown toxin responsible for the disease in such a way that they become incapable of dealing with the iron which comes to them in the food, which is consequently deposited in the cells of the liver and other organs as hæmosiderin. It is, however, equally likely that the cirrhosis of the liver, like that of the pancreas and lymphatic glands, is secondary to the excessive deposit of iron pigment, which in any case must aggravate the cirrhosis. In support of this theory is the observation that a patient of mine with aplastic anæmia developed typical hæmochromatosis in the course of seven years during which he received 270 transfusions.

Primary carcinoma of the liver occurs in hæmochromatosis somewhat more frequently than in simple cirrhosis of the liver.

Symptoms.—The symptoms are those of cirrhosis and diabetes associated with pigmentation. The liver and spleen become progressively larger. Ascites may occur and the subcutaneous veins are sometimes enlarged. The skin is generally pigmented a slaty colour, especially in the exposed parts of the body. The lesion of the suprarenal cortex may give rise to symptoms of Addison's disease, the pigmentation of the skin being sometimes due to

melanin and not to hæmosiderin, and pigmentation of the buccal mucous membrane may occur. In the rare cases in which no pigmentation is present the nature of the disease is only discovered after death. In most cases symptoms of severe diabetes with acidosis appear suddenly, but they may be absent to the end.

Diagnosis.—The disease can only be diagnosed with certainty when pigmentation, diabetes and cirrhosis are associated together. When two of these conditions are present alone, a definite diagnosis is impossible. It can, however, be made with a considerable degree of probability if well-marked bronzing is associated with cirrhosis even in the absence of diabetes. In doubtful cases biopsy of a pigmented area of skin will settle the diagnosis.

Prognosis.—So long as no diabetes is present the prognosis is not worse than that of uncomplicated cirrhosis, but the onset of diabetes is always a very grave event; with insulin treatment, however, a normal life can generally be led for several years, death being finally caused by the cirrhosis.

Treatment.—The treatment is that of cirrhosis and diabetes. The latter requires large doses of insulin, with the aid of which the diet can be balanced without special difficulty.

AMŒBIC HEPATITIS AND HEPATIC ABSCESS

Ætiology.—Amœbic hepatitis is very rare before the age of 20 and is most common in the third and fourth decades. Amœbic hepatitis and amœbic abscess of the liver are invariably secondary to amœbic dysentery (*vide* p. 264). In 98 per cent. of fatal cases Rogers either obtained a history of dysentery or found amœbic ulcers or scars of ulcers in the large intestine. The patient had had dysentery in the past or was still suffering from it in about 75 per cent. of acute and subacute cases, and in an additional 15 per cent. there was a history of diarrhœa, which was doubtless a mild form of amœbic dysentery. In the remaining cases amœbic ulcers had probably been present in the cæcum or ascending colon, situations in which they do not necessarily give rise to any symptoms. Dysentery may precede the development of an abscess by months or even years—in one of my cases by 16 years. When hepatitis develops during an attack of dysentery, the latter generally becomes less severe as the inflammation in the liver progresses.

The geographical distribution of the disease is identical with that of amœbic dysentery, but as it may develop in chronic cases and long after the onset of dysentery, it is not uncommon, especially in the chronic form, among individuals who have returned to Europe from the tropics. Chronic alcoholism is an important predisposing cause.

Pathology.—The amœbæ, which collect in the thrombosed veins at the base of dysenteric ulcers, pass to the liver by the portal vein. Nothing more is known as to the pathology of non-suppurative amœbic hepatitis, as death does not occur unless an abscess forms, but the hepatic insufficiency, which is always found to be present by the lævulose test, indicates that the infection is widespread and uniform through the liver. An abscess forms if a local accumulation of amœbæ gives rise to thrombosis in a portal radicle. The circulation is obstructed and necrosis of the surrounding tissue occurs;

at the same time pus is secreted as a result of the irritant action of the amœbæ on the liver tissue. The wall of the abscess is at first formed by necrotic liver tissue, but the cavity gradually becomes limited by a fibrous capsule produced by the inflammatory reaction. In 70 per cent. of cases a single abscess is present; in nearly half of the others there are 2 abscesses, in a quarter there are 3, and in the remainder there are 4 or more. A single abscess is found five times as often in the right as in the left lobe of the liver.

The contents of the abscess consist of necrosed liver cells, leucocytes, red corpuscles, fat droplets, and generally amœbæ but no bacteria. In chronic cases all the amœbæ may have died, but they can still be found in the material obtained by scraping the wall of the abscess. In rare cases an amœbic abscess becomes spontaneously sterile, and its dried remains have been found at a post-morten examination years afterwards. When an hepatic abscess reaches the surface, adhesions form between the liver and the adjoining structures, so that the contents of the abscess may burst into the lung, stomach or bowel, or open externally without infecting the serous cavities.

Acute and Subacute Amœbic Hepatitis and Hepatic Abscess

Symptoms.—About one-tenth of the cases of acute amœbic hepatitis occurring in India are of a fulminating type, in which the whole liver is riddled with small collections of pus with no fibrous tissue separating them from the surrounding liver substance—a condition which rarely, if ever, occurs outside the endemic areas. The liver rapidly increases in size; it is very painful and extremely tender. Slight jaundice may be present. The temperature is high with rapid remissions, the rise being often accompanied by rigors and the fall by copious sweating. Leucocytosis is well marked. Death generally occurs between 6 and 18 days from the onset of symptoms.

As most cases of subacute amœbic hepatitis subside completely with injections of emetine, it is clear that in the early stages no suppuration is present. Discomfort and a sense of weight are felt in the right hypochondrium in the slighter cases, but in the more severe ones the pain may be so great that the patient is hardly able to move, and he is often unable to lie on his left side owing to the dragging pain caused by the change of position. Pain may also be referred to the right shoulder and occasionally to the right arm, especially when the upper part of the liver is involved. The liver is enlarged and tender, but the rigidity of the abdominal muscles may be so great that it is impossible to feel its edge. Pressure exerted on the lower part of the right thorax, with one hand behind and the other in front, gives rise to pain. Slight jaundice is occasionally present in the severer cases. The appetite is impaired or lost, and the patient rapidly becomes weak and emaciated.

The temperature is generally remittent, varying between 100° in the morning and 103° or 104° in the evening. In severe cases it remains high with only small remissions, but in more chronic cases, especially when the abscess bulges through the capsule of the liver and the tension within its cavity consequently falls, the fever is less marked; it may then be low, continued or relapsing, and may finally disappear. Copious sweating is

common in the more severe cases. Moderate leucocytosis is always present, and the proportion of polymorphonuclear cells is considerably increased, especially when actual suppuration has occurred; if the percentage is less than 70, simple hepatitis, and not an abscess, is probably present.

The upper part of the liver is most frequently involved, and the main increase in dullness is then in the upward direction, but the lower border is also abnormally low. The lower ribs bulge, and the intercostal spaces become wider; the edges of the ribs become less clearly defined, and the skin may be œdematous even in acute hepatitis without suppuration. At an early stage the breath-sounds become feeble and the percussion note impaired at the right base; the X-rays show that the right side of the diaphragm is abnormally high, and when suppuration occurs its movements are diminished and finally cease completely. If the diaphragm is perforated by an abscess of the liver, a pulmonary abscess, or less frequently an empyema, develops. In the former case large quantities of thick reddish pus are expectorated, and, if emetine is given, rapid recovery generally results.

An abscess in the anterior and lower part of the right lobe produces a tender tumour in the right side of the epigastrium, the lower ribs become prominent, and the lower border of the liver can either be felt or is found by percussion to be displaced downwards. A rub may be heard when an abscess reaches the surface of the liver, but it disappears on the formation of adhesions with the anterior abdominal wall. In advanced cases the skin becomes œdematous, fluctuation is present, and the abscess may open externally just below the costal margin. Less frequently the abscess reaches the under surface of the liver, when it may rupture into the duodenum or hepatic flexure. Pus is then passed by rectum, and the tumour suddenly diminishes in size. The general condition of the patient immediately improves, the temperature falls, and spontaneous recovery may follow.

An abscess in the left lobe of the liver generally gives rise to a tender tumour in the epigastrium. An abscess bulging from the lower or upper surface of the left lobe is less easily diagnosed; it may escape recognition till it ruptures respectively into the stomach, when the characteristic thick reddish pus is vomited, or into the left lung or pericardium.

In some cases the X-rays show a localised increased density in the hepatic shadow, especially if the abscess is in the left lobe or if it is large and surrounded by a thick fibrous capsule. Localised subdiaphragmatic, subhepatic and retroperitoneal abscesses are uncommon complications, and general peritonitis rarely develops.

Diagnosis.—The possibility of amœbic hepatitis or hepatic abscess should be considered whenever an individual, who has been in the East, is suffering from progressive deterioration in health with more or less pyrexia, especially if the latter is remittent and accompanied by chills and sweats, and if obscure abdominal symptoms are present.

Subacute hepatitis is most commonly confused with malaria; but the rise of temperature in hepatitis is generally in the evening instead of during the day, and the liver is enlarged out of proportion to the spleen instead of *vice versa*, leucocytosis is present with a relative increase of polymorphonuclear cells and only 2 to 4 per cent. large mononuclear cells in contrast with the normal or subnormal count with 15 to 20 per cent. large mononuclear cells found in malaria; the malarial parasite cannot be found in

the blood, and the injection of emetine is followed by improvement, whilst quinine fails to influence the pyrexia.

A localised tumour in the liver in a man who has been exposed to amœbic infection is generally an abscess and more probably amœbic than a suppurating hydatid cyst. It is elastic or fluctuating, unlike the hard solid tumour formed by a gumma and a growth.

Prognosis.—Until 1907 hepatic abscess was the second commonest cause of death in the British Army in India, but the incidence of the disease has become much smaller since amœbic dysentery has been treated by emetine injections, and the mortality has been greatly reduced since the necessity for operation has become comparatively rare owing to the frequency with which treatment is instituted in the pre-suppurative stage.

Treatment.—In acute hepatitis without suppuration very rapid improvement follows the subcutaneous injection of 1 grain emetine hydrochloride on 12 or more consecutive days; the hepatic tenderness diminishes within 8 hours of the first injection, and the temperature may fall to normal in 24 hours. As there are no definite signs which distinguish acute hepatitis without suppuration from hepatic abscess unless a definite tumour is present, no local treatment should be adopted until emetine injections have been given daily for a week without producing any improvement. Even a small abscess may be completely absorbed without aspiration after the amœbæ in its walls have been killed by subcutaneous injections of emetine.

The most satisfactory treatment of an abscess is evacuation by aspiration, emetine being injected subcutaneously in order to kill the amœbæ in the abscess wall and in any ulcers which are still present in the colon. If the pus reaccumulates, a grain of emetine hydrochloride dissolved in a fluid ounce of water should be injected into the abscess cavity after it has been aspirated. The results with this treatment are so successful that the open operation, which is frequently followed by prolonged convalescence or death owing to secondary infection, is required only in the comparatively rare cases, in which the situation of the abscess cannot be determined, or bacteriological examination of the pus obtained by aspiration shows that the abscess already contains pyogenic bacteria. When an abscess has been opened or has ruptured into the lung, stomach or bowel, subcutaneous emetine injections should be continued until the temperature has remained normal for a week.

Chronic Amœbic Hepatitis

Amœbic dysentery is almost always associated with hepatic insufficiency as demonstrated by the lævulose test, although in a large majority of cases there is no sign of hepatic disorder. As acute and subacute hepatitis and hepatic abscess are common complications of amœbic dysentery, it seems reasonable to assume that the functional deficiency of the liver in these cases is caused by a mild and latent form of amœbic hepatitis.

Symptoms.—It is not uncommon to find hepatic insufficiency in patients complaining of unfitness since returning from a country in which amœbic dysentery is endemic. Some have had definite dysentery, but others have had nothing more than a few attacks of diarrhœa, and occasionally they have never had intestinal symptoms of any kind.

The patient complains of general unfitness and is easily fatigued. Very often he rightly describes himself as liverish. He generally suffers from a constant ache over the liver. His appetite is poor, and he is pale and sallow, though generally not anæmic, and true jaundice is never present. There is no pyrexia, and the leucocyte count is normal. The whole of the exposed surface of the liver is tender, and the lower border is often more easily palpable than normal, but there is little or no enlargement. Amœbic cysts are very rarely found in the stools, but in a small proportion of cases, in spite of the absence of intestinal symptoms, the sigmoidoscope has revealed the presence of small but typical amœbic ulcers—raised red spots with a necrotic centre on a normal pink mucous membrane, very closely resembling boils on the skin. Not infrequently the cæcum and ascending colon are tender, and the stools may contain traces of occult blood, presumably the result of chronic amœbic typhlitis.

Diagnosis and Treatment.—The diagnosis is quickly confirmed by the result of treatment. The injection of 1 grain of emetine hydrochloride every night for twelve nights results in the disappearance of all symptoms, and the lævulose test shows that there is no longer any hepatic insufficiency. In one case, for example, the rise in the blood sugar was 55 mgrm. per 100 c.c. one hour after taking 50 g. of lævulose and in two hours it had only fallen 25 mgrm.; after treatment the one-hour rise was 6 mgrm. per 100 c.c., and in two hours the blood sugar was the same as before the lævulose had been taken.

Further courses of six or more injections should be given 3, 6 and 12 months later in order to prevent recurrence. This treatment is more efficacious and far less upsetting to the patient than the administration of the various other drugs which have been recommended for the treatment of amœbiasis.

SYPHILIS OF THE LIVER

Congenital Syphilis (Pericellular Cirrhosis)

Ætiology and Pathology.—The liver is affected in 50 per cent. of infants with congenital syphilis. This great frequency is probably due to the *Spirochæta pallida* passing through the placenta and the umbilical vein direct to the fœtal liver, which is the first organ it reaches, and which is consequently found to contain it in larger numbers than any other organ.

Congenital syphilis produces diffuse changes in the liver very different from the focal lesions of acquired syphilis, except in rare cases occurring in later childhood, in which caseous gummata are found. The liver is smooth and uniformly enlarged and is firmer and paler than normal. The changes are due to pericellular cirrhosis, the result of diffuse infiltration with embryonic connective-tissue cells between the individual liver cells. These may be associated with small collections of round cells, or miliary gummata, which resemble tubercles when seen by the naked eye.

The spleen is generally enlarged and hard. Diffuse small-celled infiltration or fibrosis may be found in the kidneys, pancreas, testes, suprarenal glands and lungs.

Symptoms.—Symptoms pointing to disease of the liver are not often present in infants with congenital syphilis, but on examination the liver

and spleen are found to be enlarged and abnormally firm. The liver normally extends farther down in young children than in adults owing to its relatively larger size and the more horizontal position of the ribs. Only definite enlargement and abnormal hardness of the liver can, therefore, be regarded as important in the absence of other evidence of congenital syphilis. Jaundice is rare; it may be present from birth or, less frequently, it develops a few weeks later.

Diagnosis.—The diagnosis is generally easy owing to the well-marked signs of congenital syphilis present in other parts of the body together with a positive Wassermann reaction. In the absence of such signs the diagnosis must be made from rickets, tuberculosis and gastro-intestinal infection, and, when jaundice is present, from the other more common causes of icterus neonatorum (p. 688).

Prognosis.—The prognosis depends upon the general condition of the infant. The disease is less amenable to anti-syphilitic treatment if the liver and spleen are greatly enlarged, and if hæmorrhages occur or jaundice is present. The prognosis in delayed congenital syphilis is less favourable than in acquired syphilis owing to the changes being generally more widespread.

Treatment.—The treatment is that of congenital syphilis.

Acquired Syphilis

1. *Secondary Syphilis.*—Jaundice formerly occurred in about $\frac{1}{4}$ per cent. of cases of syphilis at the same time as the roseola and enlargement of glands, but it is now almost unknown. Rapid recovery generally followed treatment with mercury, but occasionally death occurred from acute hepatic necrosis. It must, of course, be distinguished from the toxic jaundice caused by treatment with organic arsenical preparations (p. 212).

2. *Tertiary syphilis.*—**Ætiology.**—Gummata of the liver are found in only 0·3 per cent. of autopsies; but in more than half of the cases in which other active syphilitic lesions are found the liver is affected.

Syphilis affects the liver three times as frequently in men as in women. The disease is generally discovered between 10 and 20 years after infection, but in rare instances it has occurred within a year.

Pathology.—In the early stages a mass of pink syphilitic granulation-tissue, sharply separated from the healthy liver, is found; necrosis soon occurs in the centre, which becomes yellowish-white. The caseous mass is later surrounded by a fibrous capsule; as this contracts, the liver becomes more and more deformed. The capsule of the liver in the neighbourhood of a gumma is thickened, and adhesions often develop between it and the adjacent organs, the diaphragm and anterior abdominal wall. Unless they are very large, gummata are slowly absorbed till they may finally be represented by nothing more than scars, from which fibrous tissue radiates into the capsule. Gummata are generally multiple; much less often a large part of the liver is diffusely infiltrated. The condition is often associated with some degree of diffuse syphilitic hepatitis, which produces cirrhotic changes in long-standing cases, especially if the patient is alcoholic or has been treated with arsphenamine derivatives for primary and secondary syphilis.

Symptoms.—Gummata and cicatrices are sometimes found after death

without having led to any symptoms. The nature of the symptoms they produce depends upon the size, extent and position of the lesions. Before any localising symptoms appear the patient often complains of general ill-health, which is often associated with gastro-intestinal symptoms. The first symptom pointing to disease of the liver is generally pain in the right hypochondrium, the result of perihepatitis over a gumma. The pain may radiate to the right shoulder and is sometimes associated with local tenderness.

Irregularities on the anterior surface of the liver produced by gummata and by the contraction of cicatrices are easily palpable. The diagnosis from malignant disease can be made by the presence of a positive Wassermann reaction and the rapid disappearance of a gumma with anti-syphilitic treatment; jaundice and ascites are much more common in malignant disease, in which the constitutional symptoms are generally more severe, and there may be evidence of a primary growth in some other situation. In hyatid disease the liver is smooth apart from the tumour itself, but in syphilis it is often irregular, owing to the contraction of cicatrices. The presence of eosinophilia points to hydatid disease. A gumma near the gall-bladder or in the left lobe of the liver may simulate a growth of the gall-bladder or of the stomach respectively.

Irregular fever sometimes occurs. The general symptoms may simulate pylephlebitis, tuberculosis, typhoid fever or malaria, but they generally disappear under anti-syphilitic treatment. In rare cases an infected gumma may break down, when the symptoms and sequelæ do not differ from those of other forms of hepatic abscess.

Jaundice is infrequent in syphilis of the liver, but it is occasionally produced by the pressure of a gumma or of a syphilitic cicatrix; in very rare cases this is associated with attacks of pain indistinguishable from biliary colic due to gall-stones.

Ascites is uncommon, and I have seen only one case in which it was severe and recurred rapidly after paracentesis. It may result from pressure of gummata or cicatrices on the intrahepatic branches of the portal vein or less frequently on the vein itself in the portal fissure, in which cases thrombosis is likely to occur.

When a gummatous liver is associated with lardaceous disease, the clinical aspects of the latter may be so prominent that the presence of a gumma is overlooked. The liver and the spleen are enlarged, ascites and œdema are present, and the urine contains albumin and casts.

Diagnosis.—The possibility of syphilis should always be remembered in obscure hepatic disorders. Apart from a history of infection and the presence of other syphilitic lesions, the Wassermann reaction should always be tested in doubtful cases. As, however, infection with syphilis does not prove that every lesion present is syphilitic, the final proof of the nature of the disease is obtained only if great improvement or complete recovery results from anti-syphilitic treatment. The diagnosis from cirrhosis of the liver is suggested by the greater irregularity in the enlargement of the liver. Hæmatemesis, dilated veins on the abdominal wall, jaundice and symptoms of gastritis are much more common in cirrhosis, and the nutrition suffers at an earlier stage than in syphilis of the liver.

Prognosis.—The prognosis of syphilitic lesions of the liver is good if treatment is actively carried out at an early stage. In the rare cases in

which the symptoms are due to pressure exerted by cicatrices and not by gummata little or no improvement can occur.

Treatment.—As soon as the possibility of syphilis is recognised, large doses of iodide should be given. I have very rarely found ill results follow the administration of as much as 60 grains of potassium iodide every 6 hours; a patient is more likely to suffer from iodism if the dose is gradually increased from a small quantity than if full doses are given at once. Mercury should also be given, but no organic arsenical preparation should be used because of the danger of hepatic necrosis occurring as a result of its action on the already damaged liver cells.

HYDATID OF THE LIVER

Ætiology and Pathology.—Hydatid disease is produced by swallowing the ova of the echinococcus or hydatid worm (see p. 314). Food may be contaminated by the fæces of infected dogs, or infection may occur directly if an individual touches the tongue or muzzle of a dog which has been soiled with eggs from the fæces or anus of another dog. The frequency of the disease thus depends upon the number of infected dogs in a district. It is most common in Iceland and in parts of Australia and New Zealand; it also occurs in England, France and parts of Germany and Russia, but it is almost unknown in North America, except among foreigners.

When the eggs are swallowed, the embryos set free by digestion of the egg-shell pass through the walls of the stomach or small intestine into the radicles of the portal vein, by which they reach the liver, where they are generally arrested. The embryo now forms a small cyst, with an internal, nucleated, protoplasmic layer (the endocyst) and an external "cuticular membrane." The reaction in the surrounding tissues results in the formation of a fibrous capsule. After a time a dozen or more buds project from the endocyst, and develop into daughter cysts, identical in structure with the mother cyst; these soon separate from the endocyst of the mother cyst and become free.

The fluid in the cyst is clear or very slightly opalescent, with a specific gravity between 1·005 and 1·011. It contains chlorides, phosphates, traces of sulphates and succinates, and some unknown toxic substances, but only occasionally traces of albumin or sugar. Hooklets and less often hydatid heads may be found in the fluid.

The liver is involved in 60 per cent. of cases of hydatid diseases in man; a single cyst is generally present, but there are occasionally multiple cysts, or single ones may develop in more than one organ.

Symptoms.—The patient remains in good health until the weight of the cyst, its pressure on surrounding parts, or the occurrence of a complication, such as rupture or suppuration, causes symptoms. A hydatid cyst of the liver may remain latent and be discovered only after death or in the course of a routine examination of the abdomen in a patient without abdominal symptoms.

The increasing size of the liver may give rise to a sensation of weight and fullness in the right hypochondrium, and pain may be felt in the right shoulder. I have only once seen jaundice caused by pressure on the bile-

ducts and once œdema of the legs and scrotum by pressure on the inferior vena cava, but never ascites by pressure on the portal vein though this may occur in exceptional cases.

A small cyst may rupture into the biliary passages: intense jaundice results, and the patient generally develops suppurative cholangitis. A large cyst may burst into the general peritoneal cavity, especially after a blow on the abdomen. Symptoms of an allergic character may result, especially severe urticaria, erythema and pruritus. Less frequently there may be diarrhœa and vomiting, and dyspnœa, sometimes of an asthmatic character. In rare cases convulsions, collapse and cardiac failure may occur and end fatally. Rupture into the stomach or intestines may lead to spontaneous recovery.

The upper part of the right side of the abdomen and lower part of the thorax become prominent when the cyst is large. If the cyst reaches the front of the liver it becomes palpable in the hypogastrium. When it projects from the under surface, the liver is pushed forward and it may simulate a large gall-bladder or a renal tumour. A cyst near the convexity pushes the diaphragm upwards and may compress the lung and simulate a pleural effusion. In such cases the irregularity in the upper surface of the liver can be recognised with the X-rays. When deeply embedded in the liver, it produces a more general expansion and no local tumour is palpable. The tumour is generally tense and elastic. In rare cases, of which I have only seen two, percussion of the middle finger, when the left hand is placed flat over the cyst, produces a peculiar vibration—the hydatid thrill—which is almost pathognomonic. It does not, however, depend upon the presence of daughter cysts, as it has been observed in their absence and very exceptionally in other tense cysts.

Bacteria may invade the fibrous capsule and multiply between it and the cuticular membrane, with the result that the nutrition of the hydatid is impaired and the parasite dies. Its death results in a change in the cuticular membrane, which, when healthy, is impervious to bacteria and leucocytes, but now allows them to pass into the fluid, which acts as an excellent culture medium and gradually becomes filled with pus cells. Symptoms of hepatic abscess are now present, and the abscess may finally rupture into the general peritoneal cavity, stomach or intestines.

Diagnosis.—The discovery of a tumour of the liver should lead to a consideration of cancer, syphilis and hydatid cyst. The general health is greatly affected in the first, comparatively little or not at all in the second and third. In cancer and syphilis the tumour is likely to be irregular and multiple; in hydatid it is a uniform round swelling, and most frequently only one can be felt. The two former are hard and obviously solid, while the latter is elastic, and in rare cases the characteristic hydatid thrill can be felt. The Wassermann reaction is positive with a gumma and generally negative in the other diseases. Eosinophilia is frequent in hydatid, but in no other liver disease; it was known to have been present for eleven years when a patient, who proved to have a hydatid of the liver, first consulted me. The proportion of eosinophil cells may be enormous. In the case of a boy of 18, in whom the cyst had grown very rapidly, they amounted to 65 per cent. of 16,000 leucocytes per cubic millimetre; the total and differential counts fell to normal within 3 weeks of the removal of the cyst. I have

seen two cases of very large tumours of the right suprarenal, which produced a rounded protuberance on the anterior aspect of the displaced liver, closely simulating a hydatid cyst; the diagnosis was made more difficult by the presence of eosinophilia of 15 to 20 per cent. The intradermal injection of sterile hydatid fluid (Casoni's test) produces a positive cutaneous reaction in 90 per cent. of cases, and in one case of mine a pyrexial reaction lasting for three days. Once the skin has become sensitised it may remain so permanently in spite of removal of the cyst. The complement fixation and precipitin tests are less reliable.

Prognosis.—A cyst may continue to grow for as long as 20 years, but the possibility of suppuration or perforation is a constant danger. When it dies, the cuticular membrane folds on itself and may become calcified; its contents dry up and form a mass containing gritty material. It can then cause no further trouble.

Treatment.—PROPHYLACTIC.—In places where hydatid disease is common, the drinking water should be boiled, fruit and vegetables should be cooked or washed with boiled water, and care should be taken not to convey infection from dogs to food by the hands.

SURGICAL.—Hydatid cysts were formerly treated by tapping, but such methods have now been completely superseded by an open operation, in which the fluid is evacuated and as much of the cyst wall as possible is removed. In some cases the latter is very loosely attached and can be pulled out intact. The operation should be performed whenever a hydatid cyst is diagnosed, even if it causes no symptoms, as there is always a danger of serious complications.

CARCINOMA OF THE LIVER

Ætiology and Pathology.—(*a*) PRIMARY GROWTHS.—Primary carcinoma of the liver is found only about once in each thousand autopsies, and primary sarcoma is considerably rarer. Primary carcinoma may be derived from the liver-cells (hepatoma) or, much less frequently, from the bile-duct cells (cholangioma); 90 per cent. of the former and 50 per cent. of the latter occur in cirrhotic livers. Primary cancer occurs in about 7 per cent. of patients with cirrhosis, the incidence being fifty times as great as among patients free from cirrhosis. The incidence of primary carcinoma of the liver is very high in Dutch East Indies owing to the great frequency of non-alcoholic cirrhosis among the natives and to a special tendency of this form of cirrhosis to undergo malignant degeneration. Cirrhosis of the liver is a progressive lesion owing to the continuous action of the toxin, whereas in the fibrosis following subacute necrosis no further destruction of cells takes place after the original illness. Consequently the nodular hyperplasia of the latter never becomes malignant, whereas the progressive compensatory hyperplasia of the former may overstep the normal and take on the autonomous character of a new growth (*cirrhosis carcinomatosa*).

Primary cancer of the liver readily invades the portal vein, along which it spreads in both directions from the point of entry, forming a tree-like cast of the affected part of the portal system. On section the growth-distended vessels give the appearance of a tumour of multicentric origin, and dis-

semination to other parts of the liver often occurs through the portal system. In 40 per cent. of cases extrahepatic metastases are present. Spread by lymphatics may involve glands in the portal fissure, which press upon the portal vein and bile-ducts, as well as glands elsewhere in the abdomen and chest, and malignant emboli may pass by the hepatic veins to the lungs. After death the cirrhosis is found to be universal and of long standing, whereas the carcinoma appears to be of recent origin. The liver contains numerous nodules of carcinoma, which often reach the surface, but are never umbilicated. The symptoms may be indistinguishable from those of cirrhosis, the liver being normal in size or slightly enlarged. In the latter case, nodules can sometimes be felt on the surface. The spleen is often enlarged, and ascites is always present owing to portal obstruction. Pain in the right hypochondrium and jaundice are more common than in uncomplicated cirrhosis.

(*b*) SECONDARY GROWTHS.—Secondary carcinoma of the liver is about thirty times as common as primary carcinoma ; it is ten times as common as secondary sarcoma.

Secondary malignant disease occurs most frequently after the age of 50. It is more common in women than men because it frequently follows carcinoma of the breast and female genital organs, but it is rare in carcinoma of the lip, mouth and tongue, which are much more common in men than in women.

The most common seat of the primary disease is the stomach, and then in order the colon, œsophagus, pancreas and gall-bladder. It is a common sequel of cancer of the breast and uterus, and may occur when the primary disease is situated in any other organ. Cancer of the gall-bladder, extrahepatic bile-ducts and the stomach may invade the liver by direct continuity.

Symptoms.—The liver is almost always palpable, as it is enlarged and abnormally hard. It becomes progressively larger until it may be so enormous that it appears to fill the whole abdomen, the right lobe being generally most affected. The liver is irregular in shape, and individual nodules of growth are often umbilicated or depressed in the centre. Deposits of growth may be felt at the umbilicus and in the falciform ligament near the linea alba. A rub is sometimes heard over part of the liver as a result of perihepatitis.

Persistent pain is generally felt in the right hypochondrium and in the back ; it may pass to the right shoulder and occasionally down the arm. It is in part due to stretching of the capsule of the liver, especially when it grows rapidly, but the most severe pain is due to perihepatitis. Occasionally deep-seated growths, especially if primary, give rise to no pain throughout the illness.

Jaundice is present in 50 per cent. of cases owing to pressure on the main bile-ducts within the liver by the growth or on those in the portal fissure by glands. Jaundice is more frequent and more often severe in secondary than in primary growths, especially when the primary growth is in the stomach or gall-bladder, from which it has spread directly to the portal fissure. The fæces sometimes retain their colour, as the jaundice may be due to pressure on the intrahepatic bile-ducts, one or more of which escape. The jaundice is progressive and persistent, but it occasionally

develops acutely with vomiting and pain, the symptoms being indistinguishable from those of biliary colic due to gall-stones.

Ascites is present in 50 per cent. of cases. It is most commonly due to malignant peritonitis or to perihepatitis. It may also be caused by pressure on the capillaries when the liver is extensively infiltrated with growth and by portal thrombosis following invasion of the portal vein. The fluid is generally serous, and when jaundice is present it is bile-stained. Extravasation of blood into a superficial nodule may cause it to be hæmorrhagic. In rare cases it is chylous owing to obstruction of a main lymphatic, but more frequently it is chyliform. Perforation of the organ primarily involved or infection without perforation may cause it to become purulent. Œdema of the ankles is present in the late stages as a result of the toxæmia and cardiac weakness. More widespread dropsy may be caused by pressure upon or thrombosis of the inferior vena cava or some other large vein.

In the late stages the patient becomes rapidly weaker. The appetite is lost, and there is often a special distaste for meat. The body weight falls progressively, but occasionally the loss of weight due to the general emaciation is more than counterbalanced by the increase in weight of the liver and the accumulation of fluid in the abdomen. The skin is inelastic and sallow, and secondary anæmia develops. It is often possible to see the liver moving up and down with respiration through the wasted abdominal wall.

Fever is often present, especially in rapidly advancing cases, quite apart from the fever which may be caused by infection of the primary growth or of a necrotic secondary deposit. Suppurative cholangitis may be caused by the infection of ducts which have become dilated as a result of obstruction.

The large liver and the ascites may push the diaphragm up and compress the bases of the lungs, which are then likely to become congested, but the main enlargement is always downwards. The growth may spread through the diaphragm and cause hiccough and cough; pleurisy generally develops and often gives rise to a blood-stained effusion, but empyema is rare.

Finally the patient becomes somnolent and sometimes delirious. Coma is generally present during the last day or two of life; respiration becomes gradually more shallow, and death comes imperceptibly.

Diagnosis.—A painful and irregular enlargement of the liver is most frequently due to a growth, and the probability is increased if general symptoms of malignant disease are present. If there is evidence of a primary growth elsewhere or a growth has been removed by operation within the last five years, the diagnosis can be made with certainty.

The tumour produced by cancer of the liver must be distinguished from one produced by syphilis and hydatid of the liver. The shape of the liver often helps in the diagnosis, and umbilication of a nodule is conclusive evidence of cancer. The general health is much more impaired and the patient is generally older in cancer than in syphilis and hydatid disease. A history of syphilis or evidence of its effects in other parts of the body points to a gumma, and unless a primary growth is discovered the Wassermann reaction should always be tested. Whenever hydatid disease is possible, a differential blood count should be made, as eosinophilia is frequently present, but not in the other conditions. When there is much ascites it may be impossible to diagnose between cirrhosis and cancer, especially if the patient

is slightly jaundiced. The abdomen should be tapped so that the liver can be palpated; the irregularities of the cirrhotic liver are so much less marked than those in cancer that they are rarely recognisable through the abdominal wall. The spleen is generally large in cirrhosis but normal in size in cancer, and the liver is rarely very large in cirrhosis. Pain is generally more marked in cancer, and jaundice, when present, is more profound.

In secondary cancer of the liver the primary disease is often latent, especially when it is situated in the stomach, colon, tail of the pancreas, prostate and lung. But when a thorough investigation fails to reveal a primary growth elsewhere in the body, if jaundice and ascites are absent and emaciation is slight, a single, rapidly growing tumour of the liver is more likely to be primary than secondary.

Prognosis.—Cancer of the liver is always fatal. The course of primary cancer is very rapid, as it rarely lasts more than four months, and death may even occur within four weeks of the onset of symptoms. The duration of the illness in secondary carcinoma of the liver depends upon the primary disease, death being often due to the latter. If the primary disease has been removed by operation or is latent, death may not occur for a year or even longer after the disease of the liver is discovered; but most cases prove fatal within six months. The disease generally advances steadily, but it may remain almost stationary for a time and then rapidly progress to a fatal issue.

Treatment.—It is never justifiable to operate when it is known that a growth of the liver is present; but if during an operation for cancer of the stomach or gall-bladder the liver is found to be involved only in its immediate neighbourhood, an attempt should be made to remove the affected part. Moreover, the presence of one or more small nodules in the liver does not contra-indicate partial gastrectomy or colectomy for the primary growth, as the operation may be followed by a period of a year or more of complete freedom from symptoms.

The medical treatment of cancer of the liver is purely palliative, but by means of morphine the patient should be spared pain throughout the illness. An injection of morphine should be given whenever pain is felt, and the dose should be increased as the disease progresses and the patient becomes accustomed to the drug. There is no reason to fear giving very large doses several times in the day, as with their aid patients often feel perfectly happy and comfortable up to the end. The bowels should be kept regular by drugs, the dose of which generally requires to be increased as more morphine is given. The patient should be allowed to eat and drink exactly what he likes, and no restrictions should be made on account of the supposed indigestibility of certain articles of food, nor should large quantities of food be forced upon a patient who has no appetite. When the diagnosis has once been made with complete certainty, frequent examinations of the abdomen distress the patient without doing any good. If the distension produced by ascites gives rise to pain, the fluid should be removed.

ARTHUR F. HURST.

DISEASES OF THE PORTAL VEIN

NON-SUPPURATIVE PYLEPHLEBITIS AND PORTAL THROMBOSIS

Ætiology and Pathology.—The stagnation of blood caused by cirrhosis of the liver accounts for about 30 per cent. of cases of portal thrombosis, but the latter is so rare that it only occurs in about 1½ per cent. of cases of cirrhosis. Malignant disease of the liver, stomach or pancreas is the next most common cause; invasion of the veins of the affected organ leads to thrombosis, which spreads to the portal vein. Syphilitic changes in the walls of the portal vein and non-suppurative pylephlebitis caused by spread of infection from neighbouring parts may cause thrombosis.

Portal thrombosis may extend throughout the vein and its branches, but more frequently it is localised to the main trunk and one or more intrahepatic branches or extrahepatic tributaries.

Symptoms.—In the presence of cirrhosis of the liver or intra-abdominal growth, especially if ascites is present, there may be no indication that portal thrombosis has occurred. If, however, the patient is in comparatively good health, sudden occlusion of the portal vein may lead to the rapid development of ascites, hæmatemesis and melæna, and the spleen becomes enlarged. When the splenic vein is occluded, the splenic enlargement is rapid and considerable. When mesenteric veins are suddenly involved, hæmorrhagic infarction results and leads to intestinal paralysis with severe melæna and early death.

SUPPURATIVE PYLEPHLEBITIS

Ætiology.—Suppurative pylephlebitis is almost always secondary to some intra-abdominal inflammatory disease, generally associated with the presence of pus under pressure. Acute appendicitis accounts for nearly half of the cases.

Pathology.—The veins leading from the source of infection to the liver, together with the trunk and intrahepatic branches of the hepatic vein, may all be involved, but the disease is generally less extensive and may be confined by firm clots to a part of the portal vein or one of its branches. The affected veins contain pus and broken-down blood clots. Their walls are acutely inflamed and may give way, leading to the formation of abscesses. Thus a large abscess may develop in the mesentery or behind the pancreas. The liver is almost always involved by extension to the intrahepatic portal branches, or by secondary abscesses formed from infective emboli from the part of the vein primarily affected. Innumerable minute abscesses are present, many of which may coalesce to form a honey-combed appearance or large abscesses. Superficial abscesses may rupture and lead to general or local peritonitis, which may also result from the primary disease. The infection is generally caused by *B. coli*, streptococci or staphylococci, and very rarely *Bact. typhosum* or *dysenteriæ*.

Symptoms.—The onset is generally sudden, the symptoms due to the

primary disease being complicated by the occurrence of a rigor or pain and tenderness over the liver. The clinical picture is eventually a composite one of the symptoms of the primary disease, sepsis and liver disease, with the frequent addition before death of pneumonia, pulmonary abscesses or empyema, generally on the right side. Evidence of portal obstruction is rarely present. The patient looks anxious and ill. He is sallow and in about half the cases is jaundiced. The jaundice is generally slight, but may be severe from associated cholangitis. Fever is continuous, intermittent or remittent, leucocytosis is present, and the pulse and respiration are rapid. Rigors with profuse sweating are common, especially in the early stages. Uniform enlargement of the liver occurs in about 60 per cent. of cases. Pain and tenderness are generally present, and a rub may be heard over the liver. The spleen is only occasionally enlarged. Vomiting is common and diarrhœa may occur. Blood cultures are generally sterile.

Diagnosis.—The development of a septic state with rigors and enlargement and tenderness of the liver in a patient with appendicitis or other intra-abdominal disease is suggestive of suppurative pylephlebitis, but a correct diagnosis is rarely made. In amœbic abscess of the liver there is generally a history of dysentery, the progress of the disease is less rapid, and there may be signs of a single abscess instead of a uniform enlargement of the liver. A history of gall-stones is much more common in suppurative cholangitis than in pylephlebitis, and jaundice appears earlier and is deeper. The diagnosis from a sub-diaphragmatic abscess secondary to appendicitis may be impossible, and the two may be present together. Acute infective endocarditis with enlargement of the liver and spleen without cardiac murmurs closely simulates suppurative pylephlebitis.

Prognosis and Treatment.—The disease is always fatal, and no treatment is of any avail.

ARTHUR F. HURST.

DISEASES OF THE GALL-BLADDER AND BILE-DUCTS

CHOLECYSTITIS

Ætiology and Pathology.—Cholecystitis results from infection of the gall-bladder, most frequently with *B. coli*, but also with *Bact. typhosum* and *paratyphosus*, streptococci and staphylococci. The mere presence of bacteria in the bile does not necessarily lead to cholecystitis, just as bacilluria may occur without causing pyelitis. The *B. coli*, which normally inhabits the colon and lower part of the ileum, might theoretically gain access to the gall-bladder by four different channels.

(1) Typhoid bacilli pass from the intestines by the lacteals to the mesenteric glands, from which they are conveyed by the lymphatics to the thoracic duct and thence into the general circulation, a typhoid septicæmia being thus produced. The bacilli are excreted from the blood in the bile by the liver and in the urine by the kidneys probably in every case, but cholecystitis and pyelitis develop in only a comparatively small proportion. There is no

doubt that *B. coli* can pass through the healthy bowel wall, but under ordinary conditions it gets no farther than the lymphatic glands, which act as a very efficient filter, and there is no evidence that cholecystitis is ever preceded by a *B. coli* septicæmia. Even in ulcerative colitis, in which the inflamed and ulcerated mucous membrane of the colon might be expected to permit the easy passage of bacteria into the general circulation, neither septicæmia nor cholecystitis occurs.

(2) The portal vein would seem a likely channel for the passage of *B. coli* to the liver and thence in the bile to the gall-bladder without gaining access to the general circulation. But the portal blood is normally sterile and remains so even when the wall of the bowel is damaged, and bacteria injected into the portal vein of animals are not excreted in the bile.

(3) It has been suggested that cholecystitis is the result of infection with strains of streptococci having a special affinity for the gall-bladder, which are conveyed to it by the cystic artery from infected teeth, tonsils and other foci. But infection of the gall-bladder with streptococci is much less common than with *B. coli*, and later investigations have failed to confirm the experiments upon which this theory was based.

(4) Most cases of cholecystitis are probably due to an ascending infection from the duodenum. The duodenum is normally sterile, but in achlorhydria large numbers of *B. coli* and streptococci are often present. Achlorhydria is found in about 30 per cent. of cases of gall-stones. In the acute gastritis which occurs in food poisoning and influenza and other infections achlorhydria is generally present, although it is only likely to persist in association with chronic gastritis in individuals with constitutional hypochlorhydria. But observations after perforation of gastric and duodenal ulcers show that the stomach and duodenum are invaded by organisms ascending from the colon within a few hours of the appearance of the achlorhydria caused by sympathetic inhibition of secretion following the perforation. It is clear, therefore, that the duodenum may be infected during the temporary achlorhydria resulting from acute gastritis, and the infection may last sufficiently long for ascending infection of the gall-bladder to occur. It is in fact not uncommon for patients with chronic cholecystitis to date their symptoms from an attack of food poisoning or an acute infection, which may have been accompanied by achlorhydria, even if the gastric secretion when the patient comes under observation is normal. As acute gastritis is very common and few people pass through life without having one or more attacks, it is easy to understand why cholecystitis is such a common disorder.

Infection of the gall-bladder first leads to inflammation of the mucous membrane, the external appearance of the gall-bladder remaining normal. The inflammation subsequently spreads to the deeper tissues; the walls become thick and inelastic and the cystic lymphatic gland enlarged and inflamed.

Cholecystitis may be acute, subacute or chronic from the onset. Acute and subacute cases may become chronic, and suppuration or gangrene may occur in a chronically inflamed gall-bladder if a stone becomes impacted in the mouth of the cystic duct. The contents may become purulent in the course of an acute infection without gall-stones, but necrosis is very rare in their absence.

Acute Cholecystitis; Empyema of the Gall-Bladder

Ætiology and Pathogenesis. — Acute cholecystitis occurs in about 1 per cent. of cases of typhoid and paratyphoid fever. Apart from this it is rare unless the cystic duct is obstructed by an impacted gall-stone. Bile is generally present in the gall-bladder only if the contents are examined within a few days of the onset. The wall is thickened and obviously inflamed, and the cystic lymphatic gland is enlarged. When the cholecystitis is secondary to an impacted gall-stone suppuration or gangrene is likely to occur. Suppuration leads to empyema of the gall-bladder: if adhesions have previously formed as a result of chronic cholecystitis the empyema may rupture into the duodenum or colon; otherwise localised or generalised peritonitis results. Necrosis may be localised or general. When localised it is generally secondary to ulceration at the neck of the gall-bladder following impaction of a stone; rupture into the duodenum or the production of a local abscess commonly follows. The whole wall of the gall-bladder may become gangrenous as a result of over-distension from obstruction of the cystic duct or less commonly of the common bile-duct, especially in elderly people in whom the blood supply is deficient; unless cholecystectomy is promptly performed, general peritonitis is then certain to develop.

Symptoms.—Acute pain in the right hypochondrium is the most constant symptom. It often radiates to the angle of the right scapula and less frequently to the right shoulder. The gall-bladder may be felt as an extremely tender tumour, but more frequently the rigidity of the right rectus makes deep palpation impossible. Jaundice occurs only if there is a stone in the common bile-duct or the cholecystitis is part of a general infection of the biliary passages. Pyrexia with polymorphonuclear leucocytosis is always present.

The *défense musculaire* often involves the right dome of the diaphragm as well as the right rectus, signs of œdema and congestion of the base of the right lung being present.

In mild cases recovery takes place after a few days, but symptoms of chronic cholecystitis may develop at a later date. In suppurative or gangrenous cholecystitis fatal complications rapidly occur unless an early operation is performed.

Treatment.—Mild cases subside with the physiological rest provide by a lacto-vegetarian diet, the patient being kept warm in bed. In more severe cases, especially if there is a leucocytosis of more than 12,000 cells per c.mm., or if suppuration or gangrene is suspected, an operation should be performed without delay.

Chronic Cholecystitis

Symptoms.—Chronic cholecystitis is a common cause of chronic dyspepsia. The patient complains of intractable indigestion of an irregular character, in striking contrast with the clock-like regularity of the pain in duodenal ulcer. The time of onset and the severity of the pain vary greatly from meal to meal and from day to day; it sometimes begins immediately after food, and at other times it may not come until two or three hours after a meal, or it may only occur in the early part of the night. It is

unaffected or only incompletely relieved by taking food and by alkalis. In most cases the patient complains of what he calls flatulence, but this is really only a sensation of fullness, which is not associated with increased fermentation, and with eructation only when it gives rise to aerophagy by causing the patient to make repeated but futile efforts to belch in the hope of relieving his discomfort.

Nausea is common. It may occur on waking, when it is sometimes associated with vertigo, cold sweats or headaches, in which case migraine may be simulated, though the headache is not unilateral. It may be relieved by breakfast, unless eggs are eaten, when it is often aggravated. It is sometimes followed by vomiting, which gives much less complete relief than in ulcer.

Patients with ulcer generally lose all their pain in two or three days if put to bed on a strict diet, but improvement is less likely to follow in cholecystitis; the dyspepsia may, however, rapidly improve if yolk of egg and other fatty foods are prohibited. Constipation is generally present, but in some cases intermittent or continuous diarrhœa of a mild grade occurs, and in rare instances profuse, watery diarrhœa heralds the onset of an acute exacerbation.

If attacks of biliary colic, whether of the abortive or acute variety, occur in association with symptoms of cholecystitis, gall-stones are probably present.

The discomfort after meals is generally in the mid-epigastrium, but it often extends to the right and may be confined from its onset to the right hypochondrium. It is frequently associated with pain at the angle of the right scapula.

Tenderness of the gall-bladder is the most characteristic sign of cholecystitis. It is best elicited with the patient lying relaxed on his back; the fingers are then pressed beneath the right costal margin in the region of the gall-bladder. The pain is much increased when the fingers are brought into still more intimate contact with the gall-bladder by deep inspiration, which is then sharply arrested.[1] The pain produced in this way is in striking contrast with the absence of tenderness when deep pressure is exerted under the left costal margin or a short distance to the inner or outer side of the gall-bladder under the right costal margin, though it is not uncommon for a slighter degree of tenderness to be observed over the whole of the lower border of the liver, especially in the immediate neighbourhood of the gall-bladder. Pressure on the gall-bladder may also cause nausea.

The upper part of the right rectus abdominis muscle is often tender and rigid; tenderness and rigidity of the lowest intercostal muscles may cause impeded respiration and a stitch in the right side of the chest. Tenderness is also sometimes present over the third to the tenth dorsal spines, the muscles to their immediate right and the end of the eleventh rib.

In chronic cholecystitis there is generally no pyrexia, but occasionally the temperature rises to between 99° and 100° F. each evening or during exacerbations of the inflammation accompanied by more marked symptoms.

The healthy gall-bladder can be visualised with the X-rays by Graham's method (*cholecystography*). The patient is given a fat-free meal at 6 p.m. the evening before the examination, and at 9 p.m. he very slowly drinks a solution of phenoltetraiodophthalein in half a pint of water. During the following hour he sips water, but after that no further food or drink is allowed

[1] This sign was first described by Naunyn in 1892, but is often incorrectly ascribed to Murphy who described it ten years later.

until the first examination is made at the fifteenth hour. If the shadow is weak, another radiograph is taken at the eighteenth or twentieth hour. When a sufficiently clear picture has been obtained, a fatty meal, consisting chiefly of buttered eggs, is taken. If the gall-bladder has not filled at the eighteenth hour, an ordinary meal is given followed in six hours by a fat-free meal and a repetition of the whole procedure. Occasionally at the first examination the shadow of the gall-bladder is partially obscured by gas or undissolved dye in the colon; in such cases a normal saline enema should be given. The opaque dye is absorbed and excreted in the bile, in which it reaches the gall-bladder; as no further meals are taken it remains there, and as a result of absorption of water by the mucous membrane it becomes sufficiently concentrated to throw a shadow of the gall-bladder, which can be seen on the screen, and a cholecystograph can be taken. A normal gall-bladder gives a homogeneous shadow with a regular outline; it is not tender when directly palpated, and it is freely movable, being quite independent of the shadow of the duodenal bulb, which can be seen simultaneously by giving a small opaque meal. The normal gall-bladder is found to have contracted and evacuated the greater part of its contents an hour after the fatty meal. In simple cholecystitis the gall-bladder shadow is normal, but the visualised organ is found to be the seat of the tenderness previously discovered in the supposed position of the gall-bladder. Not infrequently the gall-bladder is found to be in an unusual position, and tenderness, which would not otherwise have been found, can then be elicited. If adhesions have formed, the outline may be deformed, remaining so even when contracted after a fatty meal, and it may be impossible to separate the shadow of the gall-bladder from that of the duodenal bulb. When the mucous membrane is severely damaged the shadow is either feeble or absent, though the latter is rare in the absence of gallstones, and when the muscular wall is involved both filling and emptying may be delayed.

Whenever cholecystitis is suspected, an attempt should be made to obtain some of the contents of the gall-bladder for pathological examination (*Meltzer-Lyon test*). A sterilised Einhorn tube is swallowed up to the 23-inch mark first thing in the morning before the patient has had anything to eat or drink. The stomach is emptied and washed out with sterile water. The tube is then slowly paid out up to the 28½-inch mark, which allows sufficient length for the duodenum to be reached. Samples are aspirated every quarter of an hour until the comparatively abundant, acid, turbid and colourless fluid present in the stomach is replaced by the very small quantity of neutral or alkaline, clear and generally bile-stained fluid present in the duodenum. The pylorus is generally passed in less than half an hour, but if delay occurs the sphincter can be made to relax by the introduction of magnesium sulphate. The duodenum is washed out with sterile water, and 25 c.c. of a 25 per cent. solution of magnesium sulphate are injected through the tube. This causes the gall-bladder and the bile-ducts to contract and the sphincter of the common bile-duct (Oddi's sphincter) to relax. An abundant flow of pure bile, first pale from the common bile duct and then dark from the gall-bladder, rapidly appears; this is aspirated, and the tube is withdrawn. In the absence of disease the gall-bladder bile never contains any pus cells, epithelial cells, pigment granules or cholesterol crystals, but often a little mucus; it is generally sterile, but a few bacteria may be present if the duo-

denum has not been sufficiently washed out, especially in cases of achlorhydria, in which the duodenal contents generally swarm with bacteria. In cholecystitis the quantity of mucus is greater than normal, and degenerated columnar epithelial cells, pigment granules and, less frequently, pus cells are present; the bile contains bacteria, most commonly an aberrant form of *B. coli* in pure culture, and rarely streptococci or staphylococci. In two cases of mine *Bact. typhosum* was isolated 23 and 10 years respectively after typhoid fever. The presence of a yellow liquid lipoid material in the gall-bladder contents suggests the presence of a strawberry gall-bladder. The combination of cholesterol crystals with pigment granules indicates the presence of gall-stones in 100 per cent. of cases. If large cholesterol crystals with the corners broken or rounded are found, gall-stones are almost certainly present, but small and perfect crystals are sometimes precipitated in the bile in the absence of stones.

Treatment.—The majority of early cases of cholecystitis can be cured by medical treatment, and great improvement often occurs in very chronic cases. Hexamine is excreted by the bile; whereas it acts as an antiseptic only in acid urine which sets free formalin from it, the presence of bile salts makes it active in bile in spite of its alkalinity (Knott). As a maximal concentration of the drug is required, alkalis should be given simultaneously in sufficient quantity to make the urine alkaline; by this means the production of formalin in the urine is prevented, and large doses can be given without irritating the bladder. A mixture containing 80 grains each of sodium bicarbonate and sodium citrate in 2 fl. oz. of water is given three times a day, the first dose after breakfast, the second after tea, and the third after a glass of water or milk on going to bed. When the urine, which is tested each time it is passed, has been constantly alkaline for 24 hours, 100 grains of hexamine are added to each dose of medicine. If the urine is not alkaline, the dose of alkali is increased. The patient should continue to take the 300 grains of hexamine a day for about 6 weeks. Hexamine can be given for further periods of 6 weeks if the symptoms recur. An autogenous vaccine prepared from the *B. coli* or other organism isolated from the bile may help to overcome the infection.

Stasis of bile in the gall-bladder aggravates the infection. It is fortunate therefore that thorough drainage can be assured by the oral administration of magnesium sulphate in concentrated solution when fasting an hour before breakfast. The largest quantity should be given which the patient can take without getting diarrhœa when no other aperient is used. This causes the gall-bladder and bile-ducts to empty their contents into the duodenum through the relaxed Oddi's sphincter. Olive oil in 240 minim doses should be taken three times a day half an hour before meals, as it has the same effect as magnesium sulphate on the gall-bladder.

If cholesterol crystals or liquid yellow lipoid material are found in the bile from the gall-bladder, a cholesterol-free diet should be given. No eggs and nothing made from the yolk of eggs should be allowed. Butter must be used sparingly; cream, cheese, kidney, liver, sweetbread, brain, duck, goose, suet and sausages are not allowed, and as little fat of meat as possible should be taken.

If achlorhydria is present, gastric lavage should be practised in the hope that normal secretion will be restored. If this fails, hydrochloric acid should

be given before breakfast and with lunch and dinner, but not during a course of treatment with hexamine, as it makes it difficult to keep the urine alkaline. If hyperchlorhydria is present, belladonna should be given in addition to the olive oil before meals.

If the appendix is diseased, it should be removed, and cholecystectomy should be performed at the same time, even if the external appearance of the gall-bladder is normal, as in many cases of chronic cholecystitis only the mucous membrane is obviously inflamed. Apart from this, the indication for surgery in chronic cholecystitis is the failure of medical treatment after it has been thoroughly carried out for an adequate time. If it is likely that gall-stones are present, it is generally useless to delay operation. In all cases cholecystectomy should be performed in preference to cholecystostomy.

GALL-STONES

Synonym.—Cholelithiasis.

Ætiology.—Clinically gall-stones occur about twice as frequently in women as in men, but they are found *post mortem* about five times more often in women than men. They are very rare before the age of 15; 75 per cent. of clinical cases occur between 30 and 60, 40 to 45 being the most common age. The incidence is greatest *post mortem* about 20 years later. Gall-stones occur in about 25 per cent. of all women and 7 per cent. of all men dying after the age of 25.

Pathology.—(*a*) *Infection.*—Infection of the gall-bladder leads to cholecystitis. The agglutinated bacteria, precipitated mucus and cellular debris may form the nucleus of gall-stones if excess of cholesterol or bile-pigment is present in the bile, especially if the flow from the gall-bladder is less free than it should be. The nature and the path of infection have been discussed in the description of cholecystitis (p. 722). Stones may form very rapidly: 25 faceted cholesterol stones, between $\frac{1}{8}$ and $\frac{1}{4}$ inch in diameter, were removed from a suppurating gall-bladder in a patient of mine 68 days from the onset of an attack of typhoid fever; *B. typhosus* was isolated in pure culture from the pus and from the centre of the stones.

When gall-stones have once formed, the infection frequently dies out, and the bile, stones and wall of the gall-bladder may be sterile, though the latter always shows signs of old inflammation. In other cases the organisms commonly found in cholecystitis are still present.

(*b*) *Excess of Cholesterol in the Blood and Bile.*—The majority of gall-stones contain a considerable proportion of cholesterol. Normal blood contains cholesterol, which comes from endogenous and exogenous sources. The endogenous cholesterol is produced by the constant activity of the cortex of the suprarenal glands, and by the periodic activity of the corpus luteum at each menstrual period. During pregnancy the corpus luteum produces a very large quantity of cholesterol, so that the percentage in the blood gradually increases to nearly double and that in the bile to four times the normal. The exogenous cholesterol comes from certain articles of diet; it is abundantly present in eggs and to a less extent in cream, and in liver, kidney, sweetbread and brain. The importance of hypercholesterolæmia in the pathogenesis of gall-stones has probably been exaggerated. Accurate post-mortem statistics show that the greater incidence of gall-stones in females

is not due to pregnancy, as the proportion of women with gall-stones who have borne children to those who have not is the same as the proportion among those who have no gall-stones. There is, however, no doubt that a biochemical factor must be present to explain the development of the large, solitary, pure cholesterol stones, which are occasionally found in perfectly healthy and sterile gall-bladders. Moreover, many patients with gall-stones have an instinctive distaste for eggs and animal fat of all kinds, which may date from childhood, and they know that such articles of diet are exceedingly likely to promote a "bilious attack." It is probable that some constitutional peculiarity in connection with cholesterol metabolism is an important predisposing cause of gall-stones; this would explain why only a certain proportion of individuals develop stones under apparently similar conditions.

(c) *Biliary Stasis.*—A stone is especially likely to form in the presence of infection and excess of cholesterol in the bile if biliary stasis is also present. In some cases there appears to be a congenital or acquired abnormality of the anatomical relations or of the neuro-muscular mechanism of the bile channels, which impedes the evacuation of the bile (*vide* p. 684). Deficient exercise also leads to biliary stasis.

By examining sections of gall-stones it is generally possible to get some idea of the history of their formation. Thus the centre of most is white and consists of pure cholesterol; only after the stone has reached a certain size is there as a rule any deposit of pigment and lime salts resulting from a period of infection. Then there may be a further layer of cholesterol caused by hypercholesterolæmia, possibly the result of pregnancy; then another stratum of pigment and lime salts may form, and so on. A pure cholesterol stone corresponds to a pure oxalic acid or uric acid stone in the kidney, and the presence of pigment and of lime salts corresponds to that of phosphates in a urinary stone. Pure pigment stones are always the result of infection, except in cases of acholuric jaundice, when they are secondary to excessive production of bile-pigment by hæmolysis.

Symptoms.—Gall-stones may be completely latent. More frequently their development is preceded and accompanied by continuous or intermittent dyspepsia. These "inaugural symptoms" are sometimes referred to as gall-stone dyspepsia: they are really due to cholecystitis (p. 724) and not to the presence of stones. Abortive attacks of biliary colic may occur independently of or associated with gall-bladder dyspepsia. Typical attacks of severe colic are less frequent and are uncommon in the absence of previous symptoms.

Many patients who suffer from gall-bladder dyspepsia and a few who have no such symptoms complain of short attacks of severe pain, which may occur at any time of the day or night without any obvious cause, such as an indiscretion in diet, although occasionally an attack is the direct sequel of a long railway journey, a drive in a motor-car on a bad road, or violent exercise. Attacks may occur daily or at long intervals, or there may be a series close together followed by a long spell of freedom. The patient may shiver during an attack, although his temperature never rises greatly and often does not rise at all. When the pain is acute, it is impossible to take a deep breath, the attempt producing a "catch" in the right side of the chest, which is very similar to that felt in pleurisy.

Attacks of biliary colic most frequently result from impaction of the stone in the neck of the gall-bladder close to or at its junction with the cystic duct. They often occur in the night. The attack begins with extremely sudden acute pain high in the epigastrium or in the region of the gall-bladder or both; it may pass through to the angle of the right scapula. The violent pain is accompanied by great restlessness, in marked contrast with the motionless state of a patient with a perforated ulcer, acute appendicitis or coronary thrombosis. Some relief may be obtained by pressing upon the abdomen. The patient feels cold, but sweats profusely. Slight inspiratory distress is common, but the presence of definite dyspnœa or faintness, when the pain is high in the epigastrium or still more so if it is substernal, should raise the suspicion of coronary thrombosis as an alternative diagnosis. Nausea almost always occurs; the presence of vomiting generally indicates that the stone has passed from the gall-bladder into the cystic or common bile duct. Aerophagy is generally present. The pain commonly disappears with absolute suddenness. The sudden onset and sudden cessation are specially characteristic of gall-stone obstruction in the cystic duct. The temperature may rise a degree or two during the attack, and there may be a slight temporary leucocytosis. Constipation is complete.

Jaundice occurs only when a stone reaches the common bile-duct. Repeated attacks without jaundice are generally caused by a stone of some size becoming impacted in the neck of the gall-bladder. Repeated attacks with jaundice, which may be very evanescent and sometimes completely latent and only recognisable by the temporary presence of a positive direct van den Bergh reaction, indicate the passage of small stones down the cystic and common bile ducts into the duodenum, numerous stones being generally still present in the gall-bladder. The slightest yellow tinge of the conjunctivæ or a trace of bile in the urine is strong evidence that an attack of pain of doubtful origin is due to gall-stones.

If a small stone, having traversed the cystic duct and passed down the common bile-duct to reach the ampulla of Vater, remains there owing to the smallness of the lumen of Oddi's sphincter, a special group of symptoms appears. In two-thirds of the cases one or more stones are still present in the gall-bladder. A stone in the ampulla acts as a ball-valve causing intermittent attacks of colic with incomplete jaundice. Pain is rarely absent; it is occasionally the only symptom. Vomiting is common in the attacks, which are accompanied by fever with chills or severe rigors in 50 per cent. of cases. The jaundice is rarely complete and persistent; it is occasionally absent, but in such cases van den Bergh's test generally gives a positive direct reaction showing that hyperbilirubinæmia is present; in rare cases it is unaccompanied by pain. In the intervals between attacks the patient may appear to be quite well, though a slight degree of jaundice or some residual pain in the gall-bladder region may be present. Sooner or later ascending cholangitis is likely to develop; there is then constant pyrexia with repeated rigors and polymorphonuclear leucocytosis.

Small gall-stones are rarely recognised in the stools and larger ones are very rarely passed. It is important to distinguish gall-stones from concretions produced by drugs or by the administration of large quantities of olive oil. The majority of gall-stones consist of cholesterol and can, therefore, be recognised by being very light and inflammable. The rarest form of stone to

be passed is a very small rounded one, which has probably traversed the normal passages during an attack of colic; as it may be the only one, a cure may result. More frequently faceted stones are passed; even if large numbers are found, it is very unlikely that all have left the gall-bladder. Lastly one, or less frequently two or three large stones, which may be formed by the agglomeration of several smaller ones, may be passed after traversing a fistulous communication between the gall-bladder and duodenum or colon. The fistula may develop very slowly without symptoms after chronic cholecystitis has led to the production of adhesions. More frequently the perforation appears to be sudden and takes place during or after an attack of colic. In other cases the fistula may be caused by the perforation of an empyema of the gall-bladder into the bowel. In rare cases a large stone may cause acute intestinal obstruction, generally near the end of the ileum. Occasionally the pain in the neighbourhood of the umbilicus or the right iliac fossa disappears spontaneously as the stone passes onwards; pain may be subsequently felt below the umbilicus and finally in the rectum, from which it may have to be dislodged by the finger. The complete passage may take from 1 to 8 days.

It is generally impossible to palpate the gall-bladder during an attack of acute pain owing to the rigidity of the abdominal muscles, but when the attack passes off the tenderness generally becomes localised to the gall-bladder itself. In some early cases the gall-bladder is found to be enlarged owing to distension with clear fluid, especially if the stone is impacted in the cystic duct. It gradually contracts on the stone or stones within it, probably after temporary dilatation, so that in long-standing cases it is rarely palpable. Even if a gall-stone passes into the common bile-duct, the gall-bladder does not often become enlarged; thus a large gall-bladder in a case of chronic jaundice generally indicates chronic pancreatitis or a growth of the head of the pancreas or of the common bile-duct.

Pure cholesterol gall-stones are never visible with the X-rays, but when much lime salts are present, especially in thin patients, they often throw a characteristic "ring" shadow. The shadow must be distinguised from that produced by a renal calculus, a calcified tuberculous focus in a kidney, a calcified tuberculous gland or a calcareous deposit in a costal cartilage. This can now be easily done by means of cholecystography. This method also makes it possible to photograph transparent stones, as they are often seen as pale areas surrounded by the dark shadow formed by the dye filling the rest of the gall-bladder. Failure to produce a cholecystograph on two successive occasions, especially in the presence of a good shadow of the liver, which proves that the dye has been absorbed from the intestines, indicates that the cystic duct is obstructed, probably by an impacted stone, that the lumen of the gall-bladder is entirely occupied by stones, or that its mucous membrane is so damaged that it is incapable of absorbing water and so producing the concentration of the bile necessary for the production of a shadow.

In doubtful cases valuable information can often be obtained by the Meltzer-Lyon method (p. 726). Failure to obtain dark bile on injecting magnesium sulphate into the duodenum would confirm a diagnosis of gall-stones suggested by absence of a gall-bladder shadow after cholecystography. The presence of large, broken cholesterol crystals with or without pigment granules is conclusive evidence of gall-stones, and other abnormal constituents may point to the presence of cholecystitis (p. 726).

Complications.—Cholecystitis is always present before gall-stones develop, except with the rare solitary sterile cholesterol stone. If the mouth of the cystic duct becomes obstructed suppuration or gangrenous cholecystitis may develop (p. 723). In some cases inflammation may spread up the hepatic ducts or down the common bile-duct; in the latter case the pancreatic ducts may become infected and chronic pancreatitis develops. In rare cases glycosuria or actual diabetes follows. Cancer of the gall-bladder or bile-ducts occurs in about 4 per cent. of people over 40 with multiple-faceted gall-stones compared with 0·4 per cent. of those with no gall-stones and with solitary cholesterol stones. The former are secondary to chronic cholecystitis, the latter to some metabolic disorder: the carcinoma is, therefore, presumably a result of the chronic cholecystitis, together perhaps with a direct chemical or mechanical carcinogenic action of the stones on the inflamed mucous membrane.

Treatment.—During an attack of biliary colic the pain should be controlled by the injection of morphine (gr. $\frac{1}{4}$) with atropine (gr. $\frac{1}{150}$). Slight attacks may be relieved by a tablet of glyceryl trinitrate (gr. $\frac{1}{100}$) placed under the tongue.

The early recognition and thorough treatment of cholecystitis can be regarded as a true method of prophylaxis of gall-stones.

Treatment of cholecystitis may also result in the solution or washing away of cholesterol deposited on the walls of the gall-bladder and of minute agglomerations of crystals—the basis of what might later become gall-stones. Moreover, even when definite stones are present it may cause the accompanying indigestion, the so-called gall-bladder dyspepsia, which is really due to the cholecystitis, to disappear. However, if the symptoms point definitely to the presence of gall-stones, and especially if repeated attacks of severe biliary colic have occurred, an operation should be advised, unless on account of obesity or renal or cardiac complications the patient is a bad subject for operation. Myocardial disease is not, however, a contra-indication, as the cardiac condition frequently improves after cholecystectomy, and patients with impaired hearts often stand the operation remarkably well. Fat patients should be strictly dieted for 2 or 3 months in order to bring their weight down before operation. Except in urgent cases a short preliminary course of treatment with hexamine (p. 727) is always advisable before operating, and the liability to complications or the recurrence of symptoms is greatly reduced by the regular use of magnesium sulphate to prevent stagnation of bile after the operation. Whenever feasible cholecystectomy should be performed in preference to cholecystostomy, and the common bile duct should always be explored for stones even if there has never been any jaundice.

BILIARY COLIC WITHOUT GALL-STONES

It occasionally happens, especially in otherwise healthy young adults of both sexes, that typical attacks of slight or severe biliary colic, generally unaccompanied by jaundice, occur in the absence of gall-stones. During an attack and for a short time afterwards the gall-bladder is tender. The bile obtained through a duodenal tube from the gall-bladder is normal in every

way. Cholecystography occasionally reveals some abnormality in the cystic duct in the form of acute angulation with or without dilatation of the proximal segment, and pressure upon the visualised gall-bladder, especially in a direction from its vertex towards its neck, causes pain; the gall-bladder is sometimes unusually large.

On abdominal exploration the gall-bladder looks healthy, but it may be tightly distended. Examination may show some abnormality in the anatomy of the cystic duct, or an accessory cystic artery may be present, which results in kinking when the gall-bladder is in certain positions. The condition is analogous to Dietl's renal crises. Cholecystectomy is generally followed by permanent cure, though neither macroscopical nor microscopical examination shows any abnormality in its walls or contents.

When no anatomical abnormality is discovered, the condition is probably identical with that which gives rise to attacks of biliary colic after cholecystectomy for gall-stones or cholecystitis, and which leads to the assumption that a stone has been left in the common bile-duct, though at operation no stone or other cause of organic obstruction is discovered. The attacks are, I believe, caused by a disturbance of the neuro-muscular mechanism of the biliary ducts and the sphincter of the common bile-duct—achalasia of Oddi's sphincter. When the gall-bladder has been removed, the common bile-duct often dilates to form a reservoir, which to some extent takes its place; this must be due to the resistance offered by the unrelaxed Oddi's sphincter to the flow of bile, corresponding with the dilatation of the œsophagus following achalasia of the cardia. It may take a long time for the neuro-muscular mechanism of the common duct and its sphincter to adapt itself to the conditions present after cholecystectomy, and during this period attacks of pain may result from temporary obstruction by the closed sphincter when the dilated common duct is attempting to empty itself.

Diagnosis. –This condition can be diagnosed when typical attacks of biliary colic are associated with definite tenderness of the gall-bladder, cholecystography shows that no stone is present, and the bile obtained from the gall-bladder is normal. Between attacks the tenderness over the gall-bladder gradually disappears, whereas in cholecystitis it rarely goes completely. When several attacks of colic occur after cholecystectomy has been performed and the common bile duct explored for gall-stones by a competent surgeon, crises of this kind are the most probable cause.

Treatment.—Regular contraction of the gall-bladder and ducts and relaxation of Oddi's sphincter can be promoted by giving Epsom salts with belladonna when fasting in the morning and olive oil half an hour before meals. Before resorting to morphia, an attempt to relieve attacks with one or two glyceryl trinitrate tablets (gr. $\frac{1}{100}$) placed under the tongue, failing this, the injection of a large dose (*e.g.* gr. $\frac{1}{50}$) of atropine should be tried. If attacks persist the gall-bladder should be removed if this has not already been done, the bile ducts explored, and Oddi's sphincter dilated.

CARCINOMA OF THE GALL-BLADDER

Carcinoma of the gall-bladder is a rare disease, which constituted only 0·5 per cent. of the gall-bladders removed at the Mayo Clinic. It is 3 times

more common among women than men, and few cases occur before the age of 50. Calculi are present in about 75 per cent. of cases (p. 732).

Symptoms.—In 70 per cent. of cases there is a long history of repeated gall-bladder attacks. This is followed by a short phase of constant pain, accompanied by progressive weakness, anorexia and loss of weight, but no anæmia. The pain is situated in the right hypochondrium and often radiates to the right scapular region. Flatulence, nausea and vomiting are common. A tumour can generally be felt; it may at first be smooth, but later becomes hard and irregular. It is generally not very tender, and there is less muscular rigidity over it than is commonly the case with an inflamed gall-bladder.

After a time secondary deposits lead to symptoms, and in some cases these are most prominent throughout, the primary disease remaining latent. Thus the liver is often large, hard and irregular from the presence of secondary deposits. Jaundice often occurs as a result of extension to the bile-ducts or compression by enlarged glands; it is occasionally remittent or intermittent, when it is generally due to cholangitis or a gall-stone in the common bile-duct.

Ascites is present in about a quarter of the cases as a result of malignant peritonitis or pressure of glands on the portal vein. Septic complications, such as suppurative cholecystitis or cholangitis, or local or general peritonitis, may occur. Death generally supervenes within six months of the development of definite symptoms apart from those due to the preceding cholecystitis or gall-stones.

Diagnosis.—The diagnosis is often exceedingly difficult, but the presence of a hard irregular tumour in the region of the gall-bladder with pain, anorexia and loss of weight in a middle-aged or elderly individual, especially if he has had symptoms pointing to cholecystitis or gall-stones, is suggestive of a growth of the gall-bladder.

Treatment.—It is rarely possible to remove a growth of the gall-bladder owing to the difficulty in making an early diagnosis. The operative mortality is high, and a very large proportion of cases recur within six months. The presence of early carcinoma is occasionally discovered on microscopical examination of a gall-bladder removed on account of chronic cholecystitis with or without gall-stones; permanent recovery may then follow.

CONGENITAL OBLITERATION OF THE BILE-DUCTS

Ætiology.—This rare disease occurs rather more frequently in male than female infants. It is occasionally familial and is not associated with congenital syphilis.

Pathology.—Some unknown toxin probably passes from the mother by the umbilical vein to the fœtus. Part of the toxin reaches the liver direct and causes multilobular cirrhosis. The rest passes into the general circulation and reaches the liver by the hepatic artery; it is excreted in the bile and gives rise to unilobular cirrhosis and inflammation of the small and large ducts and gall-bladder, which, being extremely small at birth, become more or less completely obliterated. The disease is thus a combination of portal and biliary cirrhosis with obstruction of the ducts.

Symptoms.—Jaundice is generally present at birth, but may not appear for two or more weeks. The meconium is normal, but the stools are free from bile from the first, and the urine is deeply bile-stained. The liver and spleen are large and hard. The infant is often remarkably well till the terminal stage, when purpura and hæmorrhages from the mucous membranes and umbilicus are common and convulsions may occur.

Diagnosis.—Deep jaundice in a new-born infant with a large liver and spleen and hæmorrhages without any early evidence of infection is generally due to this disease.

Prognosis.—Life may last from a few days to as much as 11 months.

Treatment.—No treatment is of any value.

CARCINOMA OF THE BILE-DUCTS

Ætiology.—The incidence of carcinoma of the bile-ducts is about half that of carcinoma of the gall-bladder. It is associated with gall-stones in about 50 per cent. of cases.

Pathology.—The growth arises most frequently in the ampulla of Vater, where a papillomatous projection into the duodenum develops. The common hepatic duct and the common duct are next most affected; a growth of either of the two hepatic ducts is very rare. Primary growths of the cystic duct can rarely be recognised, as at the time of death they are likely to have spread either to the gall-bladder or to the junction with the hepatic duct.

Symptoms.—The first symptom is generally jaundice, which develops gradually and is often intermittent; though the fæces are clay-coloured, they generally contain a little stercobilin. Apart from loss of weight and strength the symptoms are those of obstructive jaundice, but pain may be felt in the epigastrium or right hypochondrium, and attacks of colic may occur. In a case of mine the symptoms simulated those of duodenal ulcer and there was no jaundice, as ulceration of the growth had destroyed Oddi's sphincter. The condition was recognised with the X-rays by the presence of a filling defect on the inner aspect of the descending part of the duodenum associated with a diverticulum representing the ampulla of Vater. Occult blood is always present in the stools, and the patient may become extremely anæmic. The gall-bladder and less frequently the liver is enlarged. The primary tumour is never palpable. Ascites may occur as a result of secondary malignant peritonitis or of pressure of glands on the portal vein. The course of the disease is sometimes remarkably slow; in one case of mine the patient lived for over two years after the first attack of jaundice.

The diagnosis from carcinoma of the pancreas, chronic pancreatitis and a stone in the common bile-duct is discussed on p. 741.

Treatment.—Life may be rendered more bearable as well as being considerably prolonged by cholecystenterostomy if the obstruction is in the common bile-duct. Owing to the almost insuperable technical difficulties of the operation it is very rarely possible to excise a growth of the ampulla of Vater.

ARTHUR F. HURST.

DISEASES OF THE PANCREAS

THE INVESTIGATION OF DISEASES OF THE PANCREAS

The pancreas produces an external secretion—pancreatic juice, and an internal secretion—insulin. The two functions are entirely independent, and in the diseases affecting the former, which are alone considered in this section, glycosuria due to deficient insulin is rarely present and never severe.

The pancreatic juice reaches the duodenum by the large duct of Wirsung and the small duct of Santorini. The duct of Wirsung runs by the side of the common bile-duct for a short distance and then joins it to form the ampulla of Vater, a small cavity in the wall of the descending part of the duodenum, which opens in the biliary papilla, the end of the duct being kept closed by the tonic action of Oddi's sphincter. The duct of Santorini discharges through a small papilla a short distance nearer the pylorus, but in 30 per cent. of normal individuals it is not patent or is too small to perform the functions of the duct of Wirsung if the latter is obstructed. The common bile-duct is completely surrounded by the head of the pancreas in 62 per cent. of bodies; in the remainder it lies in a more or less deep groove in the gland. It is clear from these anatomical facts that deficient pancreatic digestion may occur owing to failure of the pancreatic juice to reach the intestine either as a result of diffuse disease of the pancreas, which inhibits the activity or actually destroys the secreting cells, or as a result of obstruction caused by a gall-stone in, or a growth of, the ampulla of Vater occuring in one of the 30 per cent. of people with an incompetent duct of Santorini. The effect on digestion will obviously be the same in each case. It is further clear that in 62 per cent. of cases of chronic inflammation or cancer of the head of the pancreas jaundice will result; but, if the duct of Santorini is incompetent, jaundice accompanied by deficient pancreatic digestion may be equally well due to obstruction of the ampulla of Vater without disease of the pancreas.

The stools in deficient pancreatic digestion.—The stools are bulky and pale owing to excess of fat, the proportion of which in the dried fæces may be increased to 60 to 80 per cent. from the normal of 15 to 25 per cent. The pallor is still more marked in the presence of jaundice, as stercobilin is then absent or reduced in quantity. The fat is present chiefly in its neutral form, whereas normally only about 10 per cent. is unsplit; in rare cases it separates as oil, which solidifies on cooling. Microscopically oil droplets are seen, together with crystals of fatty acids and soaps, which are formed by bacterial decomposition of the undigested fat, but the proportion of neutral fat to fatty acids and soaps remains high, in contrast with the excess of the latter and small proportion of the former in the fatty diarrhœa caused by deficient absorption (p. 626). Fragments of undigested meat can sometimes be recognised with the naked eye, especially if the presence of excess of fat is prevented by giving a fat-free diet; striated muscle fibres are always recognisable with the microscope, but there is often no excess of undigested starch. In severe diarrhœa associated with rapid passage through the small intestines the stools may contain some excess of undigested fat, meat and starch in the absence of pancreatic disease.

The irritating products of bacterial decomposition of undigested fat and meat may give rise to diarrhœa; in such cases excess of mucus is often present.

Pancreatic ferments in the duodenal contents, fæces and urine.—The duodenum normally contains trypsinogen, which is converted into active trypsin by the enterokinase of the intestinal juice amylopsin (diastase) and steapsin (lipase). Under the conditions already described, in which no pancreatic juice reaches the intestine, the ferments cannot be isolated from the duodenal contents obtained through an Einhorn tube; but it is impossible to recognise with certainty a simple reduction in the quantity present, owing to the great variations which normally occur and the technical difficulties in the quantitative estimation of the ferments. The same is true with regard to their presence in the stools, but a rough estimate of the quantity of pancreatic juice secreted can be made by measuring the tryptic activity of the fæces. On the other hand, the quantity of diastase present in the urine is fairly constant and not difficult to estimate. In destructive disease of the pancreas it is not reduced, as the ferment is apparently formed in the liver and simply excreted by the pancreatic juice. Consequently in acute pancreatic necrosis the diastase index is increased from the normal of between 6 and 30 units to 200 or more, and in many cases of subacute necrosis and of growth of the head of the pancreas, especially during exacerbations which manifest themselves by increase in pain, it is increased to a less extent, a unit being the number of cubic centimetres of 0·1 per cent. starch solution digested by 1 c.c. of urine. The index is low in renal disease owing to deficiency in the excreting power of the kidney.

Carbohydrate metabolism.—Although the secretion of insulin is rarely much affected in the disease of the pancreas considered in this section, a rise in the blood sugar with or without slight glycosuria is sometimes observed, and the glucose tolerance test may show some deficiency in carbohydrate metabolism. In doubtful cases this is a strong point in favour of pancreatic disease.

In very rare cases an adenoma or carcinoma develops from the cells of the islands of Langerhans and gives rise to hyperinsulinism with symptoms of hypoglycæmia, indistinguishable from those produced by an overdose of insulin.

ACUTE NECROSIS OF THE PANCREAS

Synonym.—Acute Hæmorrhagic Pancreatitis.

Ætiology.—The pressure under which bile is secreted is about 30 mm. to 100 mm. higher than the maximal pressure attained in Wirsung's duct after a meal, when pancreatic secretion is most active. Bile is not, however, forced into the pancreas, as the normal tone of Oddi's sphincter is overcome by a pressure of only 100 mm. But when the mouth of the common bile-duct is obstructed, the bile is forced into Wirsung's duct. The bile salts activate the pancreatic zymogens: the trypsin causes necrosis with secondary hæmorrhage of the pancreas, and the steapsin causes fat necrosis. If the bile is infected, but not otherwise, suppuration of the pancreas occurs simultaneously.

The obstruction is caused by a gall-stone in 50 per cent. of cases, and in

very rare instances by a pancreatic calculus or a round worm. When the lumen is free, the obstruction is probably caused by spasm of Oddi's sphincter secondary to acute gastro-duodenitis, which may be caused by acute corrosive poisoning. Necrosis of the pancreas may also follow a direct injury to the pancreas producing hæmorrhage.

Very rarely infection reaches the pancreas by way of the blood stream in pyæmia and infective endocarditis, and abscesses may result from retrograde thrombosis in suppurative pylephlebitis. Acute pancreatitis has been observed in influenza, typhoid fever and small-pox. It is a rare complication of mumps, but suppuration and necrosis never occur (*vide* p. 165).

Pathology.—Necrosis, hæmorrhages and suppuration are present in varying proportions in the pancreas. Opaque white areas of fat necrosis are found in the fat of the pancreas, the retroperitoneal tissue, omentum and mesentery, and also occasionally in that of more distant parts, such as the pericardium, to which the pancreatic lipase has been conveyed by lymphatics. Bacteria, especially *B. coli* and streptococci, can generally be isolated from the pancreas and often from the gall-bladder. The peritoneal cavity often contains bloodstained fluid, especially in the lesser sac; in the later stages this fluid is infected and suppurative peritonitis may be present.

Symptoms.—Without any warning a sudden very violent pain is felt in the epigastrium. It continues without intermission, but paroxysms of still more severe pain occur from time to time. Severe pain across the back is often present. After a short time vomiting begins and is repeated at frequent intervals; the gastric contents are first ejected, and after a time the vomit contains bile. Flatus may be passed, but the bowels are not opened, and no sounds indicating gastro-intestinal activity can be heard on auscultation. The abdomen soon becomes distended; it is very tender on palpation, but the muscles are often not correspondingly rigid. The tenderness and rigidity begin in the epigastrium, but before long become general. In rare cases the enlarged pancreas can be felt, but the rigidity of the abdomen generally makes this impossible. Slight jaundice is occasionally present as a result of pressure of the swollen pancreas on the common bile-duct. The patient soon becomes collapsed with a weak and rapid pulse and slight cyanosis; he appears more severely ill in the first few hours than is generally the case in acute peritonitis. The temperature is not greatly raised and may be subnormal, and leucocytosis is generally absent. Dyspnœa is occasionally observed. Glycosuria is rare, probably because death occurs too rapidly, as the diabetes produced in animals by the removal of the pancreas often does not develop until some days have elapsed. The diastase index of the urine is always raised above 100 and generally above 200.

Diagnosis.—The possibility of acute pancreatic necrosis should be considered in all cases of acute symptoms in the upper part of the abdomen in adults, especially if the patient is an elderly obese, alcoholic individual, who has previously suffered from symptoms which might have been due to gall-stones or gastro-duodenal catarrh. A carefully taken history may reveal the fact that the patient has previously had one or more similar, but much slighter attacks, probably due to acute but localised necrosis from which complete recovery took place. The symptoms may closely resemble those following perforation of a gastric or duodenal ulcer, but in the latter there is generally a history pointing to the presence of an ulcer before the onset of

acute symptoms; vomiting is continuous in pancreatitis, but occurs only at the onset or not at all in perforation, and the hepatic dullness does not alter in pancreatitis, but often disappears owing to the escape of gas through a perforated ulcer; and the abdominal muscles are generally less rigid in pancreatitis than in perforation. In other cases acute intestinal obstruction is simulated, but flatus generally continues to be passed, the abdomen is less distended, and intestinal sounds disappear at once instead of being unusually loud at first. A rise in the diastase index to 100 or more is conclusive evidence in favour of acute pancreatitis. At the operation the discovery of fat necrosis at once makes the diagnosis clear.

Prognosis.—The most acute cases are always rapidly fatal unless an operation is performed. Some cases run a subacute course, especially if one or more localised abscesses form; the illness may then continue for a week or lead to chronic pancreatitis.

Treatment.—An operation should at once be performed in all cases of acute pancreatic necrosis, except in those complicating mumps, the pancreas being drained at the site of greatest damage. If gall-stones or cholecystitis are present the gall-bladder should also be drained. The earlier the operation is performed, the greater is the prospect of recovery, but permanent deficiency of pancreatic secretion may follow.

SUBACUTE NECROSIS OF THE PANCREAS

Pathology and Symptoms.—Necrosis may occur in very small areas of the pancreas as well as in the generalised form just described. This condition is most frequently associated with gall-stones and with penetrating gastric or duodenal ulcer. It gives rise to recurrent attacks of mid- or left-sided epigastric pain, which tends to radiate round the left costal margin or to bore through to the muscles immediately to the left of the lower dorsal spine, when it may simulate renal colic. It may spread upwards to the left shoulder and downwards to the left iliac fossa and even to the left thigh and leg. The attacks generally occur two or three hours after food, when the functional activity of the pancreas is at its height. The pain may be associated with deep tenderness, but there is little or no rigidity, and the abdomen is often much distended. The patient may be perfectly well in the intervals between attacks. As in acute pancreatic necrosis, the attacks are often associated with cyanosis and a weak, though not specially rapid, pulse.

The stools are generally normal, and there is no constant glycosuria, but there may be temporary hyperglycæmia and glycosuria during the attacks.

Diagnosis.—Attacks of left-sided pain occurring in cholelithiasis and after cholecystectomy are generally caused by subacute pancreatic necrosis, which may also account for pain boring through to the back in gastric and duodenal ulcer, though I have seen very severe pain of this kind in which the ulcer was found at operation to be free from adhesions and the pancreas healthy. The sudden violent abdominal pain, with tenderness, rigidity and leucocytosis, which may occur in an attack of diabetic coma, is probably of similar origin.

Treatment.—The recurrence of attacks may be prevented if a diet is given which affords as complete rest as possible to the pancreas. The patient should be starved for 3 days and then given carbohydrates alone for 3 days. After that a more liberal diet is allowed, but fats and meat should be given very sparingly in spite of the fact that the stools show no evidence of pancreatic insufficiency.

In severe attacks the question of operation requires consideration: gall-stones, if present, should be removed and the gall-bladder drained but not excised.

CHRONIC PANCREATITIS

Ætiology and Pathology.—Chronic pancreatitis is generally due to infection spreading up Wirsung's duct. This is most likely to occur if the pancreatic secretion stagnates owing to obstruction of the duct, especially in an individual in whom the duct of Santorini is insufficiently developed to drain the gland. A small gall-stone impacted in the ampulla of Vater obstructs the mouth of Wirsung's duct and generally leads to chronic pancreatitis; if impacted in the terminal part of the common bile-duct, this complication may also occur, especially in an individual in whom the duct is completely surrounded by the head of the pancreas.

In rare cases the duct is obstructed by a pancreatic calculus, but this is probably itself a result of catarrh of the pancreatic ducts. Cancer of the head of the pancreas, and obstruction of the mouth of the common bile-duct by cancer of the ampulla of Vater or of the duodenum, are generally complicated by chronic pancreatitis, as the flow of pancreatic juice is obstructed.

When no obvious obstruction is found to account for chronic pancreatitis, the disease may be due to a gall-stone which has been passed, but the infection can also ascend from the duodenum, or descend from the upper biliary passages, as non-calculous cholecystitis is sometimes present. The cases which occur in alcoholic individuals are probably secondary to gastro-duodenal catarrh, and a typhoidal infection of the bile passages probably accounts for the occurrence of chronic pancreatitis as a sequel of typhoid fever. When a chronic gastric or duodenal ulcer erodes the pancreas, the neighbouring part of the gland becomes chronically inflamed.

In chronic pancreatitis the inflammation and the fibrosis to which it gives rise are mainly interlobular, coarse bands of connective tissue, often visible to the naked eye, separating the lobules of the gland from each other. The head of the pancreas is generally most affected; it is hard and somewhat enlarged.

Symptoms.—In chronic pancreatitis the normal functions of the pancreas must be more or less disturbed, but in the majority of cases it is entirely latent, as it is rare for the inflammation to be sufficiently severe and widespread to interfere seriously with pancreatic digestion. It is generally found accidentally during an operation for gall-stones, or at autopsy if the primary disease proves fatal. In an individual in whom the pancreas completely surrounds the common bile-duct jaundice is likely to develop. It is generally the only symptom, and chronic painless obstructive jaundice, developing insidiously without any of the initial symptoms characteristic

of catarrhal jaundice, is more often due to chronic pancreatitis than to carcinoma. The gall-bladder is dilated unless chronic cholecystitis has made relaxation of the walls impossible, but it is generally difficult to recognise by palpation, and the liver is often enlarged and abnormally hard, but not tender. In the rare cases in which pancreatic indigestion is present, the stools contain excess of fat and undigested meat (p. 623) and diarrhœa may result; the deficient digestion causes very gradual emaciation with increasing weakness. In exceptional cases diarrhœa is severe, emaciation is rapid and extreme, and there is complete anorexia.

Diabetes rarely results from chronic pancreatitis, but it may occur in very chronic cases if the inflammation spreads into the lobules and invades the islands of Langerhans.

Though chronic pancreatitis itself does not give rise to pain, severe attacks of colic are occasionally observed as a result of attacks of subacute necrosis even in the absence of gall-stones. The pain tends to radiate along the left costal margin, and to bore through to the muscles immediately to the left of the lower dorsal spine and to the angle of the scapula. Left-sided pain of this kind in gall-bladder disease should suggest the possibility that the pancreas is involved, and in chronic gastric and duodenal ulcer that penetration into the pancreas has occurred.

Diagnosis.—It is rarely possible to determine with certainty whether chronic pancreatitis is present as a complication of gall-stones or of the other conditions with which it may be associated. If hyperglycæmia with or without glycosuria develops in such a case, it is extremely probable that the pancreas is becoming affected. The changes in the fæces, which result from the absence of pancreatic digestion, do not prove that the pancreas is affected in a case of chronic jaundice, as in individuals in whom the duct of Santorini does not function obstruction of the ampulla of Vater may prevent the pancreatic juice as well as the bile from reaching the duodenum, although the pancreas is healthy.

The possibility of chronic pancreatitis should be considered in all cases of chronic jaundice in which the cause is doubtful. If the jaundice is preceded by symptoms of acute febrile gastro-duodenitis, catarrhal jaundice is the most likely diagnosis. Attacks of pain, even in the absence of a characteristic history, make the presence of gall-stones probable. In the absence of such attacks, especially if the gall-bladder be enlarged, either chronic pancreatitis or a growth is probably present. A growth is much more commonly associated with chronic pain, and emaciation and weakness develop more rapidly than with chronic pancreatitis. It is often impossible, however, even at an operation, to distinguish between a growth of the head of the pancreas and chronic pancreatitis; only when a patient recovers completely and permanently is it possible to be certain that the condition was inflammatory.

Prognosis.—The prognosis depends upon that of the primary condition in secondary cases, and the presence of chronic pancreatitis does not alter the outlook in operations for gall-stones. In cases of apparently primary pancreatitis complete recovery has taken place after an exploratory operation in which nothing was done. Chronic pancreatitis causes death only in the presence of complications. In one case death followed peritonitis secondary to rupture of the distended gall-bladder the day before an operation was to

be performed. In another the patient, who had suffered from painless jaundice for six months, refused operation, and death resulted from gastro-intestinal hæmorrhage, the exact source of which could not be found at the autopsy; it was apparently secondary to subacute necrosis of the liver, which had resulted from the long-continued biliary stasis.

Treatment.—It is only necessary to consider the treatment of those cases which appear to be primary, as when the pancreatitis is secondary no treatment beyond what is necessary for the primary disease is required. If the jaundice does not abate within three months, or a shorter period if the patient rapidly loses weight and strength or the lævulose test shows that the functional efficiency of the liver is becoming impaired, an operation should be performed. A cholecystenterostomy will cure the jaundice, remove one source of irritation of the pancreas by draining the infected bile, and prevent the development of secondary inflammation and necrosis in the liver.

SYPHILIS OF THE PANCREAS

The pancreas is affected in 20 per cent. of cases of congenital syphilis in the newborn; in most cases the liver is simultaneously affected, and somewhat less frequently the spleen, bones, lungs and other organs. The gland is enlarged and hard owing to proliferation of the interlobular connective tissue; the gland-cells atrophy, but the islands of Langerhans escape.

Syphilis in adults occasionally gives rise to chronic pancreatitis, and much less frequently to gummata of the pancreas.

Symptoms.—The symptoms are those of chronic pancreatitis or carcinoma of the pancreas. The tumour may be palpable, and it may lead to obstruction at the pylorus or duodeno-jejunal flexure with persistent vomiting. The occurrence of diabetes in a syphilitic patient should suggest that the pancreas may be affected. The Wassermann reaction should always be tested in cases of suspected chronic pancreatitis and carcinoma of the pancreas, whether the diagnosis is made clinically or at an operation, and in diabetes, and anti-syphilitic treatment instituted if it is positive.

PANCREATIC CALCULI

Pathology.—Between five and ten calculi are generally found, but in rare cases one only or as many as 300 may be present. They are white, yellow or brown, and vary in size from mere sand to smooth or irregularly shaped masses, an inch or more in length. Although pancreatic juice contains no calcium carbonate, this is the chief constituent of the calculi, which consequently throw much more definite shadows than gall-stones with the X-rays. Calculi never form in a healthy pancreas; they result from infection of the ducts and stagnation of the secretion. The ducts behind the calculi are dilated, and chronic pancreatitis is present, but suppuration is very rare. The condition may be associated with gall-stones.

Symptoms and Treatment.—Pancreatic calculi are very rare. I have seen two cases, which correspond with the two clinical types recorded in the literature, both of which may be associated with diabetes. (1) A woman

of 55 had had fatty diarrhœa for five years and her weight had fallen from 10 to 7 stone. Excess of neutral fat and striated muscle fibres were present in her stools. She had recently had an aching pain under both costal margins, especially the left. The X-rays showed multiple opacities in the region of the pancreas. She was given a fat-free diet and large doses of hydrochloric acid, as the pancreatic disorder was associated with achlorhydria. She gradually improved during the following year, and for the last ten years has been completely free from symptoms. Presumably the hydrochloric acid led to the formation of secretin, which stimulated the secretion of pancreatic juice sufficient to break down and dislodge the very friable calculi. (2) A man of 31 had attacks of severe pain in the right hypochondrium exactly simulating biliary colic; they had begun ten years earlier and recently two or more occurred daily. Nothing short of morphine gave relief. There was no jaundice. The X-rays showed a normal gall-bladder but shadows of pancreatic calculi. There was no diarrhœa, but the stools contained excess of neutral fat and striated muscle fibres and very little trypsin. At operation the pancreas was very large and hard. As the stones could not be found, an attempt was made to crush them by squeezing the pancreas. After temporary improvement the attacks recurred, severe diabetes developed, and the patient died within a year from acute pulmonary tuberculosis.

PANCREATIC CYSTS

Ætiology and Pathology.—Simple obstruction of the pancreatic duct leads to atrophy of the secreting tubules and not to the formation of cysts. When chronic pancreatitis is also present retention cysts may develop.

Hydatid cysts may develop in the pancreas, and congenital cystic disease, generally associated with cystic disease of the kidneys, may occur.

A single large pancreatic cyst may contain as much as 14 pints of fluid. Multiple cysts of various sizes, often quite small, may occur. The contents are generally turbid and dark reddish-brown or yellow. The fluid is alkaline, slightly viscid and albuminous, and may contain altered blood; microscopically degenerated epithelial cells, leucocytes, and occasionally crystals of cholesterol and rarely of leucin and tyrosin are found. The pancreatic ferments are often absent, especially in old cysts.

A large proportion of so-called pancreatic cysts are really pseudo-pancreatic cysts, being collections of fluid in the lesser sac of the peritoneum, the foramen of Winslow having been occluded by peritonitis. About a quarter of these cases follow an injury to the pancreas, which causes the escape of blood and pancreatic juice into the lesser sac with secondary peritonitis. In the remaining cases serous fluid collects slowly as a result of local peritonitis secondary to pancreatitis, the condition being analogous to a pleural effusion following pneumonia.

Symptoms.—There are often no symptoms when the tumour is accidentally discovered. In other cases symptoms due to the disease which gave rise to the cyst may precede its discovery. When the cyst has reached a considerable size there may still be no symptoms, but sometimes attacks of epigastric pain, which may radiate to the left shoulder, occur; they are

sometimes accompanied by vomiting, wasting and jaundice. Diabetes rarely develops.

The tumour is generally in the centre of the upper part of the abdomen, but it often extends farther to the left than the right. It does not move on deep respiration and is only very slightly movable in each direction. As it grows it extends farther down and may finally appear to fill the entire abdomen. It is smooth, rounded and elastic; a thrill is often produced on striking it.

Its relation to the stomach and colon can be readily determined by means of the X-rays after a barium meal and enema. It is first behind the stomach, but as it enlarges it generally reaches the anterior abdominal wall between the stomach above and the transverse colon below. Less frequently it comes forward above the stomach or below the transverse colon between the leaves of the mesocolon. It generally grows very slowly, but sudden enlargement may result from hæmorrhage into it.

Diagnosis.—There ought to be no difficulty in diagnosing a pancreatic cyst from ascites and from a hydronephrosis, enlarged gall-bladder, ovarian cyst or distended bladder. It is impossible to distinguish a true pancreatic cyst from a pseudo-pancreatic cyst clinically; even at an operation the distinction may be impossible. Mesenteric cysts are generally more movable than pancreatic cysts.

Treatment.—The cyst should be emptied and drained by operation. It is never wise to attempt to remove it owing to the dense adhesions which often fix it to its surroundings. The immediate results of operation are very satisfactory, but a recurrence is not uncommon.

CARCINOMA OF THE PANCREAS

Ætiology.—Primary carcinoma of the pancreas is a fairly common disease. The pancreas may also be invaded by direct spread of a growth of the stomach; less frequently a small secondary deposit is found when the primary disease is situated in some distant situation. Cancer of the pancreas occurs three times as frequently in males as in females.

Pathology.—The head of the pancreas is involved in 75 per cent. of cases. Cancer of the head of the pancreas obstructs the duct, which becomes dilated and occasionally forms retention cysts. The stasis of the pancreatic secretion frequently leads to chronic pancreatitis and very rarely a pancreatic calculus. Secondary deposits are often found in the neighbouring lymphatic glands, the liver and peritoneum, and less often in more distant organs.

Symptoms.—When the head of the pancreas is involved, jaundice is generally present owing to pressure on the common bile-duct, but the latter may escape if it is not embedded in the gland. The jaundice increases until it is very intense, bile being then completely absent from the fæces. The gall-bladder is almost always distended and is generally palpable; the liver is also generally large and hard. When the growth is confined to the body or tail of the pancreas there is no jaundice unless the duct is compressed by a secondary deposit, and neither the gall-bladder nor liver is enlarged. The patient complains of a dull, growing, aching pain deeply

situated in the upper abdomen and extending to the back. It is constantly present, and unrelated to meals and the bowels. In some cases it is paroxysmal. It is generally bilateral, but occasionally confined to the left, and tends to be worst at night. The pain may simulate that produced by a spinal tumour and is probably caused by involvement of the cœliac plexus. Wasting is rapid in almost all cases, and the patient becomes progressively weaker. If the head of the pancreas is involved, the stools may have the characteristic described on page 736, and diarrhœa is likely to occur, but a growth of the body or tail does not interfere with digestion. Severe constipation is common.

A tumour of the head of the pancreas is not often palpable, as it is deep-seated and likely to be hidden by the enlarged liver and the ascites, which is present in a third of the cases as a result of malignant peritonitis or pressure on the portal vein. A tumour of the body or tail of the pancreas is more often palpable, especially shortly before death when emaciation is extreme. It forms a hard, fixed mass extending across the abdomen on a level with the umbilicus, especially to the left, and is generally not tender. A tumour of the pancreas can be visualised by radiography in the lateral position by inflating with 500 c.c. of air a rubber balloon fixed to the end of a Ryle tube introduced into the stomach.

Insomnia, depression, anxiety and restlessness may be so prominent and so out of proportion to the abdominal pain, which may even be absent, that a primary neurosis may be diagnosed.

Diagnosis.—Chronic jaundice due to carcinoma of the head of the pancreas must be diagnosed from chronic pancreatitis, a gall-stone in the ampulla of Vater, and carcinoma of the ampulla of Vater. Pain is absent in chronic pancreatitis and the general health is very little impaired, whereas in carcinoma pain radiating to the back or in the back alone is often present, and there is a steady deterioration in health. A gall-stone rarely reaches the ampulla of Vater without a preceding attack of colic, whereas jaundice is generally the first symptom in carcinoma of the head of the pancreas; the jaundice in the former is often incomplete and intermittent instead of complete and permanent, pyrexia is common, and rigors may occur owing to infection of the bile passages. In carcinoma of the ampulla of Vater the jaundice, which is accompanied as in carcinoma of the pancreas by dilatation of the gall-bladder, is less complete and more intermittent than might be expected; it can sometimes be recognised with the X-rays by the characteristic filling defect it produces in the duodenum, and it always leads to the presence of occult blood in the stools.

In the absence of jaundice the possibility of a growth of the tail of the pancreas should be considered in a patient whose general condition suggests that he is suffering from cancer, but in whom no evidence of disease can be found in the organs most commonly affected. The possibility is converted to a probability if he complains of severe pain boring through to the left side of the back or a fixed tumour becomes palpable. A normal diastase index and stools showing no deficiency in fat or meat digestion do not militate against the diagnosis.

Prognosis.—Death generally occurs within six months of the onset of symptoms and is rarely delayed beyond a year.

Treatment.—If there is the smallest doubt about the diagnosis in a case of chronic obstructive jaundice, an exploratory laparotomy should be

advised. If a growth of the pancreas is found, a cholecystenterostomy should be performed in order to relieve the jaundice and thus save the patient from one of the most distressing of his symptoms. Moreover, in numerous instances permanent recovery has followed this operation when performed for a supposed growth of the pancreas, the surgeon having mistaken chronic pancreatitis for a growth. No operation can be of any use in the absence of jaundice, even in the rare cases in which a correct diagnosis is made.

ARTHUR F. HURST.

VISCEROPTOSIS

Ætiology and Pathology.—Visceroptosis is most frequently due to a fall in intra-abdominal pressure, caused by weakness of the abdominal and pelvic muscles, the normal tone of which maintains the viscera in position. The tone of the abdominal muscles is often impaired by the stretching which they undergo during pregnancy. After parturition the sudden diminution in the volume of the abdominal contents is so great that a considerable fall in intra-abdominal pressure occurs, as the stretched muscles are at first very lax. If the patient remains in bed for a sufficient period, they gradually regain their tone, and the separated recti come together again, but otherwise they become permanently weakened. Weakness of the abdominal muscles is common among people who take too little exercise.

The pelvic floor consists of a muscular diaphragm, which is formed by the levator ani and other muscles. These are often damaged in difficult labour.

When the intra-abdominal pressure is abnormally low, the viscera drop directly gravity comes into play, but at first they regain their normal position as soon as the individual lies down. At a later stage, when the daily descent of the viscera has continued for a considerable time, the displacement persists in the horizontal position.

The degree of ptosis of the different organs depends upon their weight and upon the length and elasticity of their peritoneal attachments, which, in the absence of their natural support, act as true ligaments.

True visceroptosis must be distinguished from the "hyposthenic habitus," a constitutional condition common in women, but comparatively rare in men, which is characterised by a long narrow chest and a small epigastric angle. In this the viscera are congenitally lower than in the average individual, owing to the relatively small capacity of the upper part of the abdominal cavity.

Symptoms.—Most of the symptoms of visceroptosis occur only when the erect position is assumed. They consequently disappear on lying down and are absent at night. They are temporarily relieved when the lower part of the abdomen is compressed by means of the hand, and in women they frequently show a steady improvement as pregnancy advances owing to the rise in intra-abdominal pressure and the support given to the viscera by the growing uterus. They are often worse in the later part of the day than in the morning owing to the progressive relaxation of the abdominal muscles resulting from fatigue.

The symptoms have been ascribed in turn to the kidneys, stomach, intestines and uterus, according to which happened to be the special object of study. It is certain, however, that the general effects are commonly of much more importance than those due to ptosis of individual organs.

GASTROPTOSIS.—Gastroptosis is uncommon, and even when present it is rarely the cause of symptoms. The normal stomach varies greatly in length. In the erect position it swings between the œsophagus, where it passes through the diaphragm, and the junction between the movable duodenal bulb and the descending retro-peritoneal portion of the duodenum. In a stomach of average length the umbilicus (or inter-iliac line) is about half-way between the lesser and greater curvatures. The greater curvature of the short hypersthenic stomach does not reach the umbilicus. On the other hand, in the long stomach, which is particularly common in individuals with a hyposthenic habitus, the lesser as well as the greater curvature is below the umbilicus, and the latter may reach the true pelvis. This condition has generally been called gastroptosis, but, as it is congenital and the stomach has never occupied a higher position, the name is quite inappropriate. Moreover, the long stomach is just as competent as a short one or one of average length.

When the abdominal muscles become weak, a long stomach is likely to be more affected than one of ordinary length, and a short one does not drop at all. But the gastroptosis caused in this way does not lead to kinking of the pylorus, as the pyloric end of the stomach together with the first part of the duodenum is surrounded by peritoneum and is freely movable. It may, however, give rise to a kink where the first part of the duodenum joins the second or descending part, as the latter is situated behind the peritoneum and is less mobile. Discomfort may then occur, which begins during the meal and reaches its greatest intensity as soon as all the food has been taken. It depends more upon the quantity than the quality of the food, milk producing just as much disturbance as an equal weight of solid food. Much more commonly, however, the duodenum drops with the stomach, so that a considerable degree of gastroptosis may be present with little or no gastric disturbance. It is thus always necessary to note the position of the duodenum as well as that of the stomach during an X-ray examination: if the upper extremity of the duodenum is not at least an inch above the umbilicus, duodenal ptosis is present.

After having found the position of the stomach and duodenum in the erect and horizontal positions, it must next be determined whether the stomach evacuates its contents in a normal manner. If the duodenum drops with the stomach, the passage of food out of the stomach and through the duodenum is generally normal in rate. This is also sometimes the case even if the duodenum has not dropped, but more frequently, especially if the ptosis is well marked, it can be seen with the X-rays that, although the food may pass without difficulty from the stomach into the first part of the duodenum, there is delay in the passage beyond this point.

A second examination should be made 6 hours after the opaque meal, no food having been taken in the interval. The patient should not lie down, but should follow his ordinary occupation. Gastric stasis is present if the stomach still contains food at this second examination. In order to decide whether this is due to the ptosis, a second opaque meal should be given on another day, and the patient should lie on his right side in the interval between

the two examinations. If the ptosis is the sole cause of the stasis, the stomach will be empty in 6 hours, and if an intermediate examination is made it will probably be found to be already empty in 2 or 3 hours. If there is no delay in the evacuation of the stomach in the erect position, the indigestion is not due to the gastroptosis.

It is important to observe whether voluntary contraction of the abdominal muscles in the erect posture is sufficient to raise the stomach to its normal position, as if this is the case the prognosis is good, and abdominal exercises together with the temporary use of a support will probably result in a cure. If the stomach cannot be raised to the normal position in this way, the back should be supported by the left hand whilst the lower part of the abdomen is pressed inwards and upwards with the right. In most cases this results in raising the stomach to the normal position, which indicates that an abdominal support is likely to give relief, though it will not by itself cure the condition.

ENTEROPTOSIS (COLOPTOSIS).—Ever since Glénard drew attention to the condition he called "enteroptosis," which has also been named Glénard's disease, this has been erroneously supposed to produce kinks of the intestines, especially at the flexures of the colon, and to give rise to obstruction to the onward passage of fæces. I have seen a pelvic cæcum in almost as large a proportion of strong healthy individuals, especially females, with perfect digestion and no constipation as of constipated patients. The colon, like the stomach, varies greatly in length. When the ascending colon is unusually long the cæcum is situated in the pelvis even on lying down. The lowest part of the transverse colon of normal people is almost always situated well below the umbilicus in the erect position. When it is longer than the average, as it is in most people with a long stomach, it reaches the true pelvis. Under these conditions neither a pelvic cæcum nor a pelvic transverse colon can be regarded as a result of ptosis. The position of the colon varies greatly in the course of the day: it is lowest when full and highest when empty just after defæcation; it is depressed by a full stomach; and a pelvic cæcum and transverse colon are raised out of the pelvis by a full bladder. In normal individuals examined with the X-rays the hepatic and splenic flexures often appear to be acutely kinked. This is the result of the shadow being cast in a single plane, as the limbs of the flexures belonging to the transverse colon are in front of those of the ascending and descending colon respectively, and the flexures appear to be acute, although they form a wide angle when looked at from the side.

The constipation, which is often associated with visceroptosis, is generally due to interference with the voluntary part of the act of defæcation caused by the weakness of the abdominal and pelvic muscles, and the ptosis of the diaphragm. Ptosis of the transverse colon never leads to kinking at the hepatic flexure, as the cæcum and ascending colon drop with it. A true kink is occasionally produced at the splenic flexure, as the phrenico-colic ligament is stronger than any other of the intestinal attachments. A dragging pain together with a sense of distension may then be felt in the left hypochondrium, but no serious obstruction to the passage of fæces ever occurs.

The characteristic bulging of the lower part of the abdomen and retraction of the epigastrium seen on standing are due mainly to ptosis of the small intestine, but are of no clinical importance.

HEPATOPTOSIS.—When the liver drops it rotates towards the right, or less frequently it falls forward so that its upper surface bulges in the epigastrium. The condition can be recognised by palpation and percussion, the upper border of the hepatic dullness being abnormally low. A palpable liver is thus not necessarily an enlarged one, but may simply be displaced. It gives rise to no special symptoms except occasionally a vague discomfort in the right hypochondrium which may radiate towards the shoulder; it is increased by jumping, walking and coughing, and disappears on lying down.

A *dropped spleen* can be distinguished from a large spleen by the fact that it can be manipulated into its normal position, where it is no longer palpable; it generally gives rise to no symptoms, but in very rare instances great pain is produced by twisting of its pedicle.

For *nephroptosis*, see p. 1346.

When the pelvic floor is weak, it allows the *pelvic viscera* to drop, and retroflexion of the uterus generally occurs simultaneously; it may also result in actual prolapse of the uterus and rectum.

Downward displacement of the *diaphragm* results in dyspnœa, as, being constantly in the position of extreme inspiration, it is no longer possible for its normal respiratory excursions to occur. This is particularly noticeable in patients with weak hearts, whose abdominal muscles have been stretched by an accumulation of ascitic fluid which has since been absorbed or tapped. The downward displacement of the diaphragm is accompanied by a similar displacement of the heart, which gives rise to no special symptoms.

Under normal conditions the abdominal wall and pelvic floor are the only support of the viscera; the peritoneal folds help to maintain them in position, but they do not support their weight. If, as a result of weakness of the muscles of the abdominal wall and of the pelvic floor, the viscera drop when the individual is erect, a pull is exerted on the peritoneal folds, which become true suspensory ligaments. Their sensory nerves are constantly stimulated, the patient often complaining of vague abdominal discomfort, which is generally described as a weight or pressure or as being of a dragging nature; it is relieved by lying down and by pressure upon the lower part of the abdomen. The discomfort is most marked in neurasthenic individuals owing to the irritability of their nervous system; if the nervous system is healthy it may be completely absent. It is increased by exercise and physical fatigue and to a less extent by mental fatigue.

Visceroptosis leads to an alteration in the centre of gravity of the body. In order to maintain the upright position certain muscles of the spine which are ordinarily little used are brought into action; this is a frequent cause of chronic backache.

The maintenance of the circulation when the erect position is assumed depends to a considerable extent upon the tonic contraction of the abdominal muscles. When this is deficient, as it is in visceroptosis, the abdominal veins dilate and the pulse becomes abnormally accelerated on standing; giddiness and syncope may also occur.

Treatment.—Much can be done to prevent visceroptosis in women by proper management of the puerperium. The patient should remain in bed for the first 12 or 14 days after parturition, in order that the most active period of involution of the pelvic organs should be completed before the uterine supports are subjected to strain. But when much bruising has

occurred, especially in the case of primiparæ, or when the mother is much debilitated by frequent child-bearing, this period should be extended to 3 or 4 weeks. During the whole of this time exercises for the abdominal and perineal muscles should be regularly practised under expert supervision. Most of the time during the first few days after getting up should be spent on a couch, and a return to full physical activity should be permitted only after 6 weeks.

The first indication in the treatment of visceroptosis is to raise the intra-abdominal pressure. In order to do this the condition of the abdominal and pelvic muscles must be improved. Exercise out of doors and special remedial exercises are of great value. It is essential to prevent the over-stretching of the muscles, which occurs whenever the erect position is assumed, as it is impossible for them to regain their normal postural tone so long as they have to bear the weight of the viscera for the greater part of the day. In many cases, therefore, a support is required for a time, but it should be discarded as soon as the abdominal muscles have regained their normal postural tone. An abdominal support should fit closely to the symphysis pubis and Poupart's ligaments below; it should not extend above beyond the umbilicus. It should be so made that it presses the abdominal contents upwards, backwards and inwards. In mild cases of visceroptosis in women all that is necessary is a special straight-fronted corset, which does not constrict the waist, but supports the lower part of the abdomen. In most cases, however, a light support, hinged in the middle line and fixed in position by steel springs, which pass over the hips to end in pads applied to the sacrum, is required. The abdominal support should always be put on when the patient is lying down with the pelvis raised so that the organs are held in proper position, and it should be worn all day. Not infrequently the X-rays show that the stomach and colon drop on standing almost or quite as far when the support is worn as without it. This is particularly likely to occur in cases in which an organ falls into the true pelvis, as the support does not then reach low enough, and in thin patients upon whom it is impossible to exert sufficient pressure. Such a patient, however, often derives benefit from wearing a support, although it does not hold the colon or stomach up. It acts by increasing the intra-abdominal pressure, symptoms ascribed to kinks being really the result of the low intra-abdominal pressure interfering with the circulation and with the proper performance of defæcation.

When visceroptosis is due in part to weakness of the pelvic floor, this may require treatment by pessaries and local operations, which have the object of restoring the injured parts to a more normal condition, but an exercise for the levator ani muscles is often of great value in such cases. The patient is instructed to perform the movement she would make were she attempting to overcome an urgent desire to defæcate. The exercise should be repeated about thirty times twice a day while in the recumbent position. I have often seen a tendency to prolapse of the rectum and of the uterus overcome in this way, the associated dyschezia being cured at the same time.

Gastroptosis requires treatment only in the exceptional cases in which it has led to definite gastric stasis. In slight cases the patient should lie down after meals, but in severe cases, in which there is much emaciation or the abdominal muscles are greatly atrophied, it is best for her to remain in bed for some weeks, as by this means the intra-abdominal pressure is reduced

to a minimum, and all tension is removed from the abdominal and pelvic muscles. The foot of the bed should be raised as high as possible, as this helps the organs to return to their proper position, which is often maintained after the patient gets up again, especially if she gains weight during the rest. She should lie on her right side during and for an hour after meals. She can get up to open her bowels and to wash when her stomach is empty before breakfast. Small meals should be given at frequent intervals, and food should be chosen which contains a maximum of nourishment in a minimum of bulk. Upward massage is useful, especially if the stomach or colon is low in the horizontal as well as in the vertical position; it is most effective if the masseuse gives her first treatment under the X-ray screen, so that she can see what manipulations are required to bring the stomach and colon back to their normal position. After the period of complete rest the patient should at first lie for an hour on her right side after meals.

In no circumstances should any operation be performed for raising dropped viscera. I have never seen the slightest benefit follow, and the anxious mental condition of many of the patients makes surgical interference of any kind most undesirable.

GASTRO-INTESTINAL ALLERGY

When paroxysmal attacks of abdominal pain are not obviously the result of biliary or renal colic, the possibility of abdominal allergic attacks should be considered. The pain may occur in any part of the abdomen, and its situation generally varies in different attacks. The onset is sudden, and the attack terminates abruptly after a period lasting for a few minutes to 24 or 48 hours. The patient has no abdominal symptoms of any kind in the intervals between the attacks, which may occur almost every day or not more than once or twice a year. Nothing abnormal is found on examining the abdomen between the attacks, and during the attacks there is little or no rigidity and generally little or no tenderness. The pain may be extremely severe and only partly relieved by morphine. It is often associated with vomiting and, when the pain is in the lower part of the abdomen, watery diarrhœa with or without mucus, but without blood, is generally present. The mucus may form membranes (muco-membranous colic) and in rare cases the mucus contains eosinophil cells. In some cases vomiting and diarrhœa occurs with little or no pain.

The patient often gives a family history of asthma, hay fever, skin disease or migraine, and he is often himself a sufferer from one or other of these conditions. In some cases the vomiting or diarrhœa is often or always preceded by rhinorrhœa. The abdominal attacks generally occur, however, during periods of complete freedom from other allergic manifestations, so that the frequent presence of slight eosinophilia is an important help in diagnosis. Still more characteristic is the complete relief obtained by injecting 3 to 5 minims of adrenaline (1 in 1000), as this drug has no effect on any other form of abdominal pain.

Cutaneous reactions may show that the patient is sensitive to certain articles of food, especially wheat, milk and eggs in the case of children, and pork or other pig food, cabbage, potatoes and chocolate in adults, but the

absence of such reactions does not exclude an allergic origin of the symptoms, nor does their presence prove with certainty that the articles consumed must be excluded from the diet. Sensitiveness to foods frequently consumed is rarely recognised by the patient, who is, however, generally aware of an idiosyncrasy to such articles of diet as strawberries, tomatoes, onions, spinach, cucumber, melon, shell-fish and turtle. Gastro-intestinal allergy occurs at all ages, but is most common in infants and children. In rare cases attacks are brought on by foreign proteins absorbed by the nasal mucous membrane. I have seen a typical case caused by the emanation of cats. In one patient severe attacks of abdominal pain, with vomiting and diarrhœa, were always preceded by rhinorrhœa and sometimes by swelling of the eyelids and tinnitus. The skin gave a strongly positive reaction to cat but to no foods, and it was found that the attacks occurred only at the patient's house and only during the past two years, during which she had had a cat in her room.

Treatment.—The patient should avoid any articles of food which he has found give rise to attacks, and also any which give a positive cutaneous reaction. If attacks continue to be frequent, the effect of ½ grain of ephedrine hydrochloride three times a day before meals should be tried. Nocturnal or early morning attacks may be prevented by taking 1 to 2 grains of phenobarbitone and an additional dose of ephedrine on going to bed. The patient should learn to give himself adrenaline, and at the first sign of an attack he should inject the smallest dose which experience shows prevents an attack: generally 3 to 5 minims are sufficient. The injection can be repeated at intervals if the attack does not at once completely disappear.

ARTHUR F. HURST.

DISEASES OF THE PERITONEUM

ACUTE PERITONITIS

Definition.—Peritonitis is the disease which results from infection of the peritoneum with bacteria. Owing to the large area of the peritoneum and its great powers of absorption the results are very severe, and because of its intimate relationship to the alimentary canal the risk of such an infection occurring is considerable.

Ætiology.—Infection may reach the peritoneum (1) from without; (2) by the blood stream; and (3) from the contained organs.

1. Infection from without is possible in the case of wounds, but is of infrequent occurrence. In most instances severe abdominal wounds injure the contained viscera also, and the consequent peritonitis is usually the result of this.

2. Infection by the blood stream is an occasional though uncommon mode of infection. In streptococcal and staphylococcal septicæmia peritonitis may occur as a terminal event; it frequently gives rise to so few symptoms, however, that its existence is unrecognised during life. When pneumococcal peritonitis complicates pneumococcal lesions elsewhere the infection is undoubtedly blood borne.

3. Infection from contained or neighbouring organs is by far the commonest cause of peritonitis. The majority of cases depend more or less directly on the passage of bacteria from within the alimentary canal owing to changes in its walls. The appendix is the most frequent seat of the primary condition. When there is no actual breach of continuity in the organ, bacteria escaping through its damaged walls generally lead to the formation of peritoneal adhesions and possibly to a local abscess. When, however, the infection is particularly virulent or the patient's resistance unusually poor, a sufficient local reaction does not take place, and spreading diffuse peritonitis results. This is commoner in children than adults, and may occasionally occur, even when the local reaction has been good, through manipulation or ill-judged surgery separating the adhesions and allowing the infection to spread. Diverticulitis and acute cholecystitis are occasional causes of this type of acute peritonitis, but more usually result in local adhesive changes. Peritonitis complicating typhoid fever in the absence of perforation, and pneumococcal peritonitis when associated with pneumococcal enteritis, have a similar origin.

In intestinal obstruction and strangulated hernia the changes which occur in the bowel wall speedily permit the passage of organisms through it to the peritoneum. This takes place first in the neighbourhood of the obstruction, but as paralysis and distension spread along the bowel, organisms can make their way through, and consequently most cases of this type are widely generalised. The infection, however, is gradual, and the reactive forces of the peritoneum have time to respond. By far the commonest organism in these cases is the *B. coli communis*, usually preceded by or accompanied by the *Staphylococcus epidermidis albus*.

Perforation of a hollow viscus into the peritoneal cavity is responsible for some of the most virulent and widespread cases of peritonitis; the lower the perforation in the bowel, the more virulent the resulting infection will be. The appendix is the commonest source, gangrene or a perforating ulcer leading to a sudden peritoneal infection before any gradual passage of organisms has had time to produce a local peritoneal reaction. Perforating ulcers of the stomach and duodenum come next in order of frequency; less common causes are perforating ulcers of the ileum, the most important of which is the typhoid ulcer, rupture of the gall-bladder, bile-ducts or ureters, and perforating wounds of any of the hollow organs, or leakage from surgical anastomoses. Abscesses of the liver, appendix, gall-bladder or Fallopian tubes occasionally burst into the general peritoneal cavity. Infection of the peritoneum may also result by direct spread from neighbouring parts. This type of case is particularly common in women, spread taking place either directly through the Fallopian tubes, or by lymphatic permeation of the uterine walls. Peritonitis is a very rare sequel to infections of the lung and pleura, although the reverse is far from unusual. In the infant an infection of the thrombosed umbilical vein may lead to peritonitis by direct spread.

Symptoms.—As acute peritonitis is almost invariably a secondary condition, its symptoms and course are subject to very considerable variations, depending not only on the nature of the primary lesion from which it arises and on the nature and virulence of the infecting organism, but also on the general condition of the patient.

1. *Acute generalised peritonitis.*—This is usually associated with the

perforation of a hollow organ or the sudden bursting of an abscess into the peritoneum, and owes its chief characters to the fact that in such cases the peritoneum is suddenly flooded with infection without any preliminary preparation. The patient may have been free from any symptoms of ill-health, and is suddenly seized with very acute abdominal pain, accompanied sometimes by a sensation of something having given way. The pain may at first be localised in position, and thus help in the diagnosis of the actual lesion; but it speedily spreads to the whole abdomen, and is followed almost at once by a feeling of syncope or collapse. Within a few minutes the patient becomes cold and pale; his features are pinched and betray the most intense anxiety; beads of sweat stand out upon the skin, and the pulse may be almost imperceptible. He complains of nausea, but does not often vomit, and his respirations are shallow and quickened. In a short time a certain amount of improvement takes place; the pulse, though rapid, is of better volume, and the pain may take on an intermittent colicky character. The abdomen is absolutely rigid, and is usually retracted, though it may be distended; it is very tender on pressure. The liver dullness is usually absent; but this is only important if an abdominal examination made at the onset of the attack revealed a normal area of dullness. These symptoms are caused by the perforation or other primary cause and the resultant flooding of the peritoneum with infective material. Occasionally they may be sufficiently severe to lead to death by themselves: but more usually they gradually merge into the symptoms of the consequent acute peritonitis itself. The latter are reactive in nature, and are due to nature's attempts to limit the process.

The patient becomes extremely restless, this being one of the most characteristic and distressing features of nearly all forms of peritonitis. Owing to the loss of fluid by sweating, vomiting and exudation, the subcutaneous tissues become shrunken and give the patient the so-called "facies Hippocratica." The tongue is dry and furred, and the teeth become covered with sordes. The pulse increases in rate and becomes thready and later running in character, and the temperature, which at first may be subnormal, rises. The abdomen is of a uniformly board-like rigidity and extremely tender. It is held immovable, respiration being entirely thoracic, and the patient lies with his knees drawn up to relieve the abdominal tension. There is usually absolute constipation, and the intestinal sounds are absent. Gradually the paralytic intestine becomes dilated, and the abdomen distended. Vomiting is early and frequent. The vomited matter is usually only small in quantity; it speedily becomes exceedingly foul, though it is rarely fæcal, and the breath is extremely offensive. The urine is scanty and may contain traces of albumin, and its passage may produce a paroxysm of pain. It usually contains a large amount of indican.

Throughout the whole course of the disease the outstanding feature is the pain. This may at first be intermittent and colicky; but as the peritonitis develops it becomes constant and agonising, being increased by the smallest movement. In spite of this the restlessness persists, the patient being unable to resist the desire to move his limbs. The pain and restlessness, with the persistent vomiting, the intense thirst, which is hardly relieved by drinking, combine to make the patient's misery extreme. The pulse increases in rapidity until it can scarcely be counted, the extremities become

cold, the eyes grow more sunken, and the features more pinched. As death approaches, the skin takes on a cyanotic hue; the persistent restlessness, the increasing voicelessness, and the remorselessly unimpaired consciousness bring death as a merciful release, even though the pain may be somewhat relieved towards the end.

The foregoing description applies to an acute fulminant case of peritonitis, running its course to death in from 24 to 48 hours; its outstanding features are a condition of profound shock and toxæmia, giving a measure of the high grade of peritoneal absorption. In the aged, and in patients with tabes or Bright's disease, the symptoms may be very atypical; pain may be but little marked, and vomiting and tenderness may be absent, while the bowels may act freely throughout. The striking restlessness, the condition of the tongue, the pulse and the ultimate meteorism will, however, usually indicate the true nature of the condition.

2. *Acute spreading peritonitis.*—This variety differs from the preceding in that the peritoneum is not suddenly flooded with infective material, but is prepared for infection by the more or less gradual spread of the condition. It accompanies many cases of appendicitis, and is a sequel of intestinal obstruction if unrelieved for a sufficiently long period. The peritoneal reaction is intense, and the coils of intestine become glued together with a sticky exudate, while pockets of pus form between them. The pain is at first localised to the region of origin; but as the infection spreads it extends until it may become generalised over the whole abdomen. It is, however, never so intense as in the preceding variety, and may be distinctly spasmodic in character. The general abdominal symptoms are also less severe, the tenderness, rigidity, meteorism and constipation being of varying grade. The aspect of the patient betokens a profound septic infection, the tongue is furred and dry, the pulse rapid, and the temperature of the hectic type. Rigors and sweats are not uncommon, and if left alone the case may terminate with fatal septicæmia, suppurative pylephlebitis, or in rare cases the pus may accumulate and burst either externally in the region of the umbilicus or into one of the hollow viscera.

3. *Pneumococcal peritonitis.*—This presents certain fairly characteristic features, which in many cases enable the nature of the infection to be correctly diagnosed from the clinical picture alone. It is far more frequent in children than in adults, and in girls than boys in the proportion of nearly 7 to 3. It occurs in a diffuse and an encysted form, depending probably on the resistance of the patient. In many cases there exists a definite pneumococcal enteritis, the organisms penetrating the wall of the bowel and so infecting the peritoneum. The predominance of the disease in girls is probably due to the female genitals being a source of infection, as the pneumococcus has been cultivated from the vagina in some instances. In the majority of cases, however, the peritonitis is part of a pneumococcal septicæmia; thus, when it is secondary to pneumococcal disease of the middle ear, local pneumococcal abscesses or pneumococcal arthritis, the blood stream appears to be the source of infection, and it probably is so also in those cases which follow pneumonia or empyema, since the physics of the upper abdomen renders a direct spread through the diaphragm unlikely.

There is a striking resemblance between the symptoms of most forms

of pneumococcal infection, a resemblance which strongly supports the view of their origin in a septicæmia. The onset is usually sudden, often accompanied by a chill and a high temperature, the pain is violent and persistent, and the prostration severe. The patient has the characteristic flush, the respiratory rate is raised, and the accessory muscles of respiration are called into play. Vomiting is frequent, and tenderness and rigidity are marked; but in place of the usual absolute constipation there is frequently profuse diarrhœa, which, associated with the other symptoms of acute peritonitis, is often almost diagnostic. In the diffuse form, unless operation is undertaken, death takes place early; but if the patient lives long enough there may be a sudden fall of temperature about the seventh day, as in pneumococcal pneumonia.

The encysted and more common variety of pneumococcal peritonitis is less severe, and shows a remarkable tendency for pus to collect in the lower abdomen. There is the same acute onset as in the diffuse variety; but the patient then appears to improve for a few days. Later, however, he gets gradually worse, the abdomen becomes distended, the diarrhœa changes to obstinate constipation, and an abscess forms in the lower abdomen and finally bursts at the umbilicus. The exudate in these cases is a greenish, odourless pus, which is sufficiently characteristic to enable the infection to be diagnosed when it is discovered at operation.

4. *Gonococcal peritonitis.*— Gonococcal peritonitis is rare; it occurs both as an acute diffuse affection of the peritoneum and as a localised pelvic inflammation. It is commoner in females than in males, owing to the ready channel for infection through the Fallopian tubes, and when it occurs in males it is usually secondary to epididymitis. The infection is generally a mixed one, the more fragile gonococcus being readily overgrown, and some cases of unexplained peritonitis, which on culture show only *B. coli*, are possibly gonococcal in origin. The symptoms do not differ in the diffuse cases from those of other forms of acute peritonitis, although the primary focus usually gives rise to symptoms. The prognosis is, however, good, and the majority of cases, even those presenting severe symptoms, recover without operation.

5. *Streptococcal peritonitis.*—Peritonitis due to the *Streptococcus* is occasionally secondary to lesions of the alimentary canal; but much more frequently it is a sequel of puerperal infections. It occurs commonly after a first delivery, and is frequently associated with retained products. Infection takes place along the lymphatics of the damaged uterus or through the Fallopian tubes, and may be localised in the pelvis; but it often gives rise to generalised peritonitis. The symptoms are characteristic, and are associated with evidence of a marked septicæmia. The abdominal walls, being already greatly stretched, do not show the usual rigidity, and extreme distension occurs rapidly. Diarrhœa is commoner than constipation, and a high temperature with rigors is usual. The uterine discharges are offensive, the milk secretion is suppressed, and the cases frequently progress to death within the first week. This type of infection is more fulminant than any other, except certain cases of perforative peritonitis.

Diagnosis.—The diagnosis of acute peritonitis is not usually difficult, except in cases where the severity of the causal condition is so great that it masks the peritoneal response, or where the peritonitis occurs in a patient

already so severely ill that no response is possible. It is often extremely difficult to make a correct diagnosis of the lesion to which the peritonitis is secondary, and in many cases this is only possible after laparotomy. The most valuable signs of acute peritonitis are the severe pain and tenderness, the rigid abdomen, the small, rapid, and thready pulse, the dry tongue, the restlessness, vomiting, and constipation, and the absence of sounds of gurgling on auscultation. Any of these symptoms may, however, be absent, and a diagnosis must be based on their occurrence in combination. In post-operative cases there is sometimes a remarkable absence of both pain and rigidity, and the all-important early recognition of the condition in these patients is often one of much difficulty.

Peritonitis is most likely to be mistaken for lead colic or acute intestinal obstruction. From the former it can be distinguished by the fact that the abdomen in peritonitis is usually extremely tender, while in colic pressure often, though not invariably, relieves the pain; in colic a blue line is present, and the red corpuscles show punctate basophilia, the pain is intermittent, and there is usually no vomiting and less extreme rigidity. From acute intestinal obstruction the diagnosis is often far more difficult, particularly since the two conditions frequently coexist. In the early stages of obstruction, before peritonitis has developed, the intermittent nature of the pain, the absence of great tenderness or rigidity, the copious nature of the vomit, and the evidence of increased peristalsis from inspection or auscultation should help to distinguish the two conditions.

In acute pancreatitis the pain is more definitely hypogastric, the patient is usually over middle age, and collapse is extreme. The menstrual history, the typical pallor, and the results of vaginal examination usually serve to indicate a ruptured tubal pregnancy, and in other acutely painful abdominal conditions the localised nature of the pain and the absence of any extreme general tenderness help to distinguish the condition from peritonitis.

The gastric crises of tabes are seldom likely to be a source of error; but the comparative absence of severe symptoms in tabetics, the subjects of peritonitis, is very apt to lead to a mistaken diagnosis.

Basal pneumonia and diaphragmatic pleurisy may lead to acute abdominal symptoms. The temperature and pulse, the raised respiration rate, and a routine examination of the chest in all cases should prevent a mistake being made.

Prognosis.—The prognosis of acute peritonitis is always grave, even with early surgical treatment. Without operation no case of acute perforative peritonitis can be expected to recover; such exceptions as have been recorded must be regarded as medical curiosities. Usually death takes place within 48 hours, though it may be delayed a week or even longer when the perforation is high in the bowel and the latter is empty at the time.

In diffuse spreading peritonitis and streptococcal puerperal infections death is almost as invariable, unless operation is undertaken; but the process is less rapid, and a small proportion of cases undoubtedly recover without surgical aid. These cases occasionally merge into a form of chronic fibro-purulent peritonitis, characterised by the progressive formation of collections of pus between neighbouring viscera, and by repeated outbursts of symptoms as other parts of the peritoneum become successively involved. This con-

dition usually terminates in fatal septicæmia, with infections in the pleura, pericardium or endocardium. The prognosis in pneumococcal cases is considerably better, as even without operation, a fair proportion recover, either with or without the formation of a hypogastric purulent collection, which may discharge at the umbilicus. In the rare gonococcal cases recovery is the rule, and the fatal cases recorded have almost invariably followed operation.

In forming a prognosis the chief importance must be placed on the degree of toxæmia and the severity of the intestinal paralysis, and to a less extent on the degree of meteorism and the frequency of the vomiting. Spontaneous bowel actions or their induction by enemata make the prognosis relatively more favourable.

The rate of rise of the pulse and its ratio to the temperature are also of importance; cases with a subnormal temperature throughout are almost always rapidly fatal.

Treatment.—The principles that must underlie the successful treatment of acute peritonitis are, firstly, the removal or limitation of the process to which the peritonitis is secondary by a thorough and speedy exploration of the abdomen, followed by closure of a perforation, removal of an appendix, or such other measures as the pathology present may indicate; secondly, drainage and relief of tension in the peritoneal cavity; thirdly, the encouragement of the normal peritoneal response and the least possible damage to its protective agencies; and, fourthly, the combating of the shock and toxæmia.

By the adoption of the Fowler position, in which the patient is propped up in bed in a sitting position, not only is infective material removed from the dangerous diaphragmatic area and brought into contact with the much more highly resistant pelvic peritoneum, but at the same time the diaphragm is relieved from the pressure of the dilated stomach and intestines.

A further important adjunct to surgical treatment is the intravenous injection of saline by the continuous drip method. This raises the blood pressure and redresses the chloride and fluid loss which has taken place, and being excreted by the peritoneum, it reverses to a certain extent the lymphatic circulation, and consequently largely prevents the absorption of toxic material as well as dilutes that already present. Gas-gangrene antitoxin is often of value in combating the toxæmia arising from the paralysed bowel.

Until a definite diagnosis has been made and operation advised and agreed to, the administration of opium in any form is definitely contra-indicated. It masks the symptoms, and by bringing to the patient and his advisers a false sense of security may lead to a fatal delay in undertaking the operation. When, however, a diagnosis has been made, and operation is agreed to, morphine is beneficial in reducing both the mental and physical symptoms while the necessary preparations are being made. Morphine as a method of treatment has been adopted more and more of recent years, the morphine being given deliberately and in doses sufficient to affect the respiration rate with the object of diminishing the activity of peristalsis, as well as of combating the shock, pain and restlessness, which help so largely to exhaust the patient's powers of resistance. It is very doubtful whether it ever prevents the response of the bowels to enemata in cases in which they would otherwise respond. If vomiting is a prominent symptom, lavage of the stomach is of value. It should, if possible, always be done before opera-

tion, as post-anæsthetic vomiting of fæcal material is a fruitful cause of fatal broncho-pneumonia. The introduction of an in-dwelling Ryle's tube through the nose, into the stomach, or even the duodenum, with frequent suction by syringe, is a valuable method of keeping the stomach and upper intestine empty.

In pneumococcal cases there is not quite the same urgency for operation, and in some cases recovery follows the use of sulphapyridine (M. & B. 693) and serum, if the pneumococcus can be typed, as it can be in some cases, from the urine. In gonococcal peritonitis, if a diagnosis can be made, conservative treatment should be followed; but if there is doubt, as there often must be, of the nature of the infection, or if the patient shows any increase of symptoms, laparotomy is the only safe course to follow.

E. G. SLESINGER.

CHRONIC PERITONITIS

Chronic peritonitis is a condition in which widespread and progressive chronic inflammation of the peritoneum occurs independently of tuberculous or malignant peritonitis.

Ætiology.—Chronic peritonitis may be associated with chronic inflammatory changes in the thorax. Effusion may occur from all the serous membranes (polyserositis); this condition is probably in most cases tuberculous. In other cases chronic peritonitis is associated with chronic mediastinitis and adherent pericardium (Pick's disease, p. 961). The peritoneum covering the liver (perihepatitis) and spleen (perisplenitis) is generally most severely involved.

Pathology.—The liver may be covered with a thick, hard and white coating of fibrous tissue, which can be peeled off to expose the smooth peritoneal surface. Perihepatitis is almost always associated with a similar thickening of the capsule of the spleen and with thickening of other parts of the peritoneum.

Symptoms.—The only important symptom is ascites. Its onset is generally gradual, but it may be acute. Frequent tapping is required, and the intervals between the performance of paracentesis tend to diminish and may finally be as short as a fortnight, when as much as a pint of fluid may be poured into the peritoneal cavity in a day.

Œdema, especially of the feet, is frequent in the late stages; it is generally cardiac or renal in origin, but may also be caused by pressure of the ascitic fluid on the inferior vena cava.

Course.—The course of the disease is very slow, death generally occurring from some intercurrent disease. The general health may remain good for a long time.

For the diagnosis and treatment, see Ascites (pp. 765, 766).

TUBERCULOUS PERITONITIS

Ætiology.—The peritoneum is involved in 15 per cent. of fatal cases of tuberculosis. Tuberculous peritonitis is rare in infants and uncommon

after 30; the majority of cases occur between the ages of 3 and 20. Boys and girls are equally liable to the disease; it is found much more frequently in women than men at operations, but more frequently in men than in women after death.

Primary tuberculous peritonitis is uncommon in children and rare in adults. It is probably due to infection conveyed by the intestines, which do not themselves become infected. More often, especially in children, the mesenteric glands become tuberculous, generally without any lesion developing in the intestines, and the peritoneum is infected from the glands. In males the primary focus may be the prostate, vesiculæ seminales or testes, and in females the disease frequently begins in the Fallopian tubes; but the latter may also be infected from the peritoneum. Although tuberculous ulcers are found in 75 per cent. of fatal cases of pulmonary tuberculosis, the peritoneum is affected in only 4 per cent. of cases. The peritoneum, the pleura and occasionally the pericardium may be involved together in the absence of any other tuberculous focus.

Pathology.—Tuberculous peritonitis may occur in three forms—the ascitic, loculated and obliterative.

1. In the ascitic form, which may be acute, subacute or chronic, miliary tubercles are scattered over the whole peritoneum, which is free or nearly free from adhesions. In chronic cases the tubercles are larger and more fibrotic than in the acute; the peritoneum is thickened and the mesentery is shortened so that the intestines are tethered to the posterior abdominal wall. This form may closely resemble malignant peritonitis.

2. In loculated tuberculous peritonitis the fluid may be clear, the condition being then intermediate between the ascitic and obliterative forms, or it may be turbid or purulent. In the latter case masses of tuberculous material separated from each other by adherent coils of intestine have broken down to form suppurating foci, which may erode the intestine or open at the umbilicus or even into the vagina.

3. Chronic obliterative, adhesive or fibrous tuberculous peritonitis may occur after absorption of fluid in the ascitic form or may develop primarily. No effusion is present, but universal adhesions obliterate the lumen of the peritoneum, all the viscera being inextricably bound together and to the parietal peritoneum.

In each form of tuberculous peritonitis the mesenteric glands are generally caseous ("tabes mesenterica") and may break down in the centre; the mediastinal glands may also become tuberculous. The omentum is often rolled into a solid mass, which sometimes contains caseous nodules.

Symptoms.—Tuberculous peritonitis is sometimes completely latent, and may be discovered accidentally during an operation for some independent disease or for a hernia, when the sac may be the only part involved.

The onset of abdominal symptoms is generally preceded by a period of ill-health; the patient loses weight and strength, his appetite is poor, and his temperature may rise slightly at night. After a time he complains of general abdominal discomfort. Constipation is common, especially in the obliterative form. In other cases diarrhœa may occur owing to tuberculous ulceration of the intestines, fistulous communications between adjacent coils of intestines or simple entero-colitis. The stools are occasionally bulky owing to deficient absorption of fat caused by obstruction of the lacteals by caseous

mesenteric glands (*vide* p. 626). The spleen and less often the liver may be enlarged. The skin, especially over the abdomen, is dry, inelastic and sometimes so pigmented that Addison's disease is simulated. In chronic cases there is sometimes no pyrexia; more often the temperature is intermittently slightly raised. In acute and suppurative cases the temperature is generally high and irregular, and the pulse is rapid. Traces of albumin may be present owing to the pressure on the renal veins caused by the large accumulation of fluid in the abdomen or to the effect of the toxæmia on the renal cells. A moderate degree of anæmia is often present, and leucocytosis develops if suppuration occurs.

In the ascitic form the abdomen gradually becomes distended. At first it is tympanitic, but after a time evidence of the presence of free fluid is obtained, but the quantity is not often very great. Less frequently a large amount of fluid collects with great rapidity; the sudden stretching of the abdominal muscles is likely to cause a considerable amount of pain. Moderate tenderness of the whole abdomen is generally present. A large accumulation of fluid may compress the inferior vena cava and give rise to œdema of the legs. The diaphragm is pushed upwards and respiration becomes shallow and thoracic. The skin over the abdomen is shiny and the veins are enlarged. The ascitic fluid is generally clear; it contains a large proportion of lymphocytes and often coagulates on standing; less frequently it is turbid or blood-stained. Tubercle bacilli are rarely found in the effusion, although they must be present, as the fluid may produce tuberculosis when injected into guinea-pigs.

In the loculated form with suppuration the abdominal pain is generally greater; attacks of colic are common, especially after exercise. The abdomen is distended and doughy; on percussion, irregular tympanitic and dull areas are found. Large caseous glands and collections of pus between adherent coils of intestines may form palpable masses, which are immobile, tender and dull on percussion. The omentum can often be recognised as a thick cord stretching across the upper part of the abdomen; the transverse colon generally forms a resonant band immediately above it, which helps to distinguish it from the lower edge of an irregularly enlarged liver. The ease with which the masses are felt varies from time to time with the amount of flatulent distension of the intestines. When an abscess is about to point at the umbilicus, the latter becomes indurated, red and tender; a similar condition is occasionally observed in pneumococcal peritonitis and in pelvic peritonitis in women. On rectal and vaginal examination thickened Fallopian tubes, enlarged glands or collections of pus may be felt.

The signs of obliterative tuberculous peritonitis are ill-defined; the abdomen gives a characteristic rubbery resistance on palpation and is generally somewhat distended. Irregular masses may be felt in it, and the peristaltic waves of the small intestines are often visible, especially in children. This does not necessarily indicate that partial obstruction is present, as it may be simply a result of the abnormal thinness of the abdominal wall.

Symptoms of tuberculous disease of other organs, especially of the lungs, pleura and intestines are often present. Generalised tuberculosis may develop at any time, especially in children. Vomiting and constipation, which suggest intestinal obstruction, may be the first symptoms of tuberculous meningitis.

In rare cases acute peritonitis may develop as a result of rupture of a softened caseous gland or perforation of a tuberculous ulcer.

When a patient recovers from tuberculous peritonitis, the tubercles and adhesions may completely disappear. More frequently localised adhesions remain, and calcified tuberculous mesenteric glands are often found with the X-rays, at operations and after death. They may give rise to confusion when the abdomen is X-rayed on account of suspected renal calculi. They do not, however, move with the shadow of the kidney with changes in posture, and the diagnosis can always be settled by pyelography. The bands, which may form from localised adhesions, occasionally cause acute intestinal obstruction, sometimes not until many years after the active disease has disappeared.

Diagnosis.—In the presence of tuberculous disease of the lungs or other organs, abdominal distension, especially if associated with ascites or irregular abdominal masses, generally indicates that tuberculous peritonitis is present. The discovery of tubercle bacilli in the sputum, and their much less common discovery in the fæces or vaginal discharge, is very strong confirmatory evidence. Ascites in children, and in females with symptoms pointing to tuberculous salpingitis, is generally due to tuberculous peritonitis.

Acute cases may at first closely simulate pneumococcal peritonitis or even appendicitis; but in non-tuberculous inflammatory exudates of the peritoneum most of the cells are polymorphonuclear leucocytes instead of lymphocytes. Ascites due to cirrhosis of the liver in children is almost always mistaken for tuberculous peritonitis; on the other hand, the ascitic form of tuberculous peritonitis in middle-aged alcoholic individuals is likely to be mistaken for ascites due to cirrhosis. When cirrhosis is undoubtedly present, ascites may still be due in part to tuberculous peritonitis; a large proportion of lymphocytes in the fluid is very strong evidence in favour of this, as the ascitic fluid in uncomplicated cirrhosis contains few except endothelial cells. In simple chronic peritonitis there is no fever and little or no pain, and the ascitic fluid contains few if any lymphocytes. The presence of irregular masses together with fluid in the abdomen generally indicates tuberculous peritonitis in children; but it is more frequently due to malignant disease in adults, especially in males. The history of the case and any evidence of tuberculous or of malignant disease in other parts of the body help to settle the diagnosis.

Fever, inflammation of the umbilicus, and the presence of lymphocytes in the ascitic fluid point to tuberculosis, whilst nodular infiltration without inflammation of the umbilicus, hard and enlarged glands in the groin or neck, and the presence of large, multinuclear cells or groups of cells in the effusion point to cancer.

Prognosis.—Recovery takes place in a large proportion of cases of the ascitic form of tuberculous peritonitis. When localised abscesses develop complete recovery is rare, and when a fæcal fistula forms death almost always follows. Prolonged fever, rapid emaciation and intractable diarrhœa are the most serious symptoms. The prognosis also depends on the severity of any tuberculous disease of the lungs or other organs which may be present. Apparent recovery is sometimes followed by a relapse, generally owing to reinfection from an unhealed primary focus, such as a tuberculous gland, appendix or Fallopian tube.

Treatment.—The patient should be kept in bed completely at rest so long as the temperature is raised. He should be in the open air all day and night when the weather permits, and if indoors an abundant supply of fresh air is essential. Heliotherapy or artificial sunlight should be employed, but care must be taken to avoid over-exposure. The mercurial ointment, which is sometimes applied on a binder to the abdomen, is probably quite valueless. Diarrhœa should be treated by a non-irritating diet, and in intractable cases by opium preparations. If fatty diarrhœa is present, fat must be excluded from the diet. With this exception, the food should be as abundant and nourishing as possible. Tuberculin has been much employed, but I am not convinced that it is of any use.

When the abdominal distension in ascitic cases gives rise to discomfort paracentesis should be performed. Nothing is gained by laparotomy. The occurrence of intestinal obstruction is an indication for operation, though it is rarely possible to do anything useful owing to the extensive adhesions present and the danger of tearing the intestines.

CANCER OF THE PERITONEUM; MALIGNANT PERITONITIS

Ætiology.—Cancer of the peritoneum is almost always secondary. The primary disease is generally in the abdomen, especially the stomach and the ovary, the peritoneum becoming involved by spread along lymphatics or blood vessels, by direct contact, or most commonly by malignant cells being set free and scattered widely over the peritoneum. The disease may also spread from cancer of the breast by the deep lymphatics of the chest and abdominal wall, and by lymphatics from malignant disease of the testis.

Pathology.—Malignant deposits may form minute tubercles, larger white non-caseating nodules or even very large masses. The parts most generally involved are the omentum, mesentery and pelvis. Chronic fibrotic changes frequently occur, and result in the omentum being rolled up and the mesentery shortened as in tuberculous peritonitis. The diaphragm is often invaded with growth, which spreads to one or both pleuræ. Acute or subacute peritonitis may occur.

Symptoms.—The symptoms are caused in part by the primary disease and in part by the secondary malignant peritonitis. As the former is generally situated in the abdomen, it is impossible to distinguish between the symptoms due to the two causes. Malignant peritonitis generally results in ascites; the fluid is clear or turbid, hæmorrhagic, chyliform, or less frequently chylous owing to obstruction and subsequent rupture of lacteals. The umbilicus is often infiltrated with growth, and nodules may be felt along the falciform ligament. Tumours are often felt in the abdomen or on rectal examination; they are sometimes too small to be palpable, and in other cases they can only be felt after the fluid has been removed. The rolled-up omentum can often be recognised as a thick transverse cord above the umbilicus. The malignant masses or peritoneal adhesions may give rise to obstructive symptoms.

Diagnosis.—The development of new abdominal tumours or ascites in a patient who is known to have cancer of the stomach or other organ is conclusive evidence that the peritoneum is involved. When there is no clear

evidence pointing to the presence of a primary malignant or tuberculous focus, it may be difficult to distinguish between tuberculous and malignant peritonitis (see p. 763). When ascites is present and no tumour is palpable, cirrhosis, simple chronic peritonitis or portal thrombosis may be simulated; the abdomen should be tapped, when a tumour often becomes palpable if malignant disease is present.

Prognosis and Treatment.—It is rare for the patient to survive for more than six months after the peritoneum becomes involved. Treatment is purely palliative. Considerable relief may follow paracentesis.

ASCITES

Definition.— Ascites is the accumulation of free fluid in the peritoneal cavity.

Ætiology.— Ascites is a constant symptom of simple, tuberculous and malignant chronic peritonitis. It occurs when there is a rise of pressure in the portal circulation; it is always present in portal thrombosis and when the portal vein is obstructed by a growth or an aneurysm, and portal obstruction is in part responsible for its presence in cirrhosis of the liver. Ascites is very common in heart failure, in which it is almost always associated with œdema of the feet. It is in part due to the same causes as the œdema, but it is also in part caused by portal congestion, and by obstruction to the lymph flow from the thoracic duct owing to the rise of venous pressure. Lastly, ascites accompanies the dropsy of Bright's disease and severe anæmias.

Symptoms.—The abdomen becomes gradually enlarged, at first in an antero-posterior direction, the costal margin being pushed forward, but at a later stage the bulging occurs in the flanks also. The stretching of the abdominal wall gives rise to a tight sensation, which may amount to actual pain if the fluid collects rapidly. It causes the muscles to atrophy and lineæ atrophicæ develop in the skin. The umbilicus becomes everted and may form a thin-walled bladder.

The rise in intra-abdominal pressure caused by the accumulation of ascitic fluid obstructs the inferior vena cava; œdema of the legs may occur, and the obstruction to the renal circulation may cause albumin to appear in the urine, the quantity of which is reduced owing to the loss of water in the ascitic fluid. Compensatory dilatation of other venous channels results: the dilatation of the veins passing between the abdominal wall and those in the falciform ligament is manifested by the development of large and prominent subcutaneous veins around and above the umbilicus; others pass from the superficial and deep epigastric veins in the middle of the groin towards the costal arch, where they join the superficial epigastric and long thoracic veins. When paracentesis is performed, the dilated veins disappear if they have developed as a result of pressure on the inferior vena cava, but not if obstruction of portal veins is the primary condition.

The diaphragm is pushed up; its excursions on respiration are reduced and dyspnœa may result. The impulse of the heart may be felt in the third intercostal space; the twisting of the heart may temporarily produce a pulmonary systolic murmur. Cardiac irregularity, palpitation and attacks of faintness may follow. The upper border of hepatic dullness may reach

the fourth, third or even second intercostal space in front; the right base is dull behind owing to the liver being pushed up and the lung compressed. A pleural effusion may be suspected, but the upper limit of dullness is altered on taking a deep breath if it is due to the liver being pushed up, and the increased dullness diminishes or disappears when the patient lies on his face; in pleural effusion the dullness is higher in the axilla than behind, but this is not the case if it is due to an abnormally high position of the liver.

The pelvis and renal regions hold a considerable amount of fluid, so that no accumulation occurs in the flanks until at least a litre is present in the abdomen. As more fluid collects, the resonant note in the flanks is replaced by dullness, but the change may be delayed if there is much gas in the colon. The level of dullness now gradually rises and spreads over the pubes towards the umbilicus. On turning from one side to the other the most dependent part remains dull. This is not, however, absolutely pathognomonic of ascites, as similar movable dullness may occur in chronic obstruction of the small intestines.

In chronic peritonitis the mesentery may be so shortened that the intestines are unable to float on the fluid; the fluid then accumulates in front of the intestines, and the highest part of the abdomen is dull.

A characteristic fluid thrill is felt when one side of the abdomen is sharply flicked by the fingers of one hand, whilst the other hand is placed flat upon the opposite side of the abdomen. When the patient is very fat or the abdominal wall is œdematous, a similar but less marked sensation may be produced; in doubtful cases the hand of an assistant should therefore be pressed perpendicularly over the middle line of the abdomen, as this prevents the transmission of the impulse through the abdominal wall, but not through the fluid contents of the abdomen.

When the liver or spleen is enlarged and hard, or when an abdominal tumour is present, the sensation produced by dipping the tips of the fingers suddenly through the fluid on to the solid organ, which jumps away from them, is most characteristic.

Diagnosis of Ascites.—Confusion has often occurred between ascites and a large ovarian tumour. The history of the development of the abdominal swelling may help the diagnosis. In many cases the outline of an ovarian tumour can be definitely felt, and its pelvic attachments can be recognised by vaginal examination. The antero-posterior enlargement is greater than the lateral bulging, whereas the reverse is the case in ascites; the maximal girth is below the umbilicus instead of at the umbilicus or above; the umbilicus, which is normally and in ascites an inch nearer the pubes than the ensiform cartilage, is proportionately farther from the pubes; and the distension on one side is often greater than the other instead of being uniform.

Diagnosis of Cause of Ascites.—In cirrhosis of the liver the fluid collects rapidly and the patient is obviously ill; in chronic peritonitis the accumulation on the first occasion is generally very gradual and the patient may be otherwise well. An enlarged spleen or the occurrence of hæmatemesis points to cirrhosis, evidence of chronic interstitial nephritis to chronic peritonitis. A patient with ascites due to cirrhosis alone rarely survives the performance of paracentesis more than two or three times, as his general health has already greatly deteriorated by the time that ascites develops. If tapping is frequently performed, chronic peritonitis is therefore probably

present, even if other evidence indicates that the patient is also suffering from cirrhosis. Tuberculous peritonitis is rare in adults, except as a complication of cirrhosis of the liver and when secondary to tuberculous Fallopian tubes. Evidence of tuberculous disease in other parts of the body, solid masses palpable in the abdomen or on rectal examination, pain and tenderness in the abdomen except over the liver, and induration and redness of the umbilicus point to tuberculous peritonitis; the fluid is generally turbid, the specific gravity is above instead of below 1015, and lymphocytes are present.

In malignant peritonitis there is generally evidence of the primary disease in some other organ, and nodules may be felt in the abdomen, in the neighbourhood of the umbilicus, or in the middle line above it, and enlarged glands may be present. The spleen is not enlarged, emaciation is generally greater than in cirrhosis, and, except when the primary disease is in the stomach, there is no hæmatemesis. A rectal and vaginal examination are particularly important, as ascites, which may recur very frequently, sometimes results from ovarian tumours. In a doubtful case the diagnosis may become clear after paracentesis, when the large hard liver and spleen may be felt in cirrhosis, and an irregular enlargement of the liver, but no splenomegaly, in cancer of the liver. In malignant disease the fluid may contain cancer cells; it is more often hæmorrhagic than in tuberculous peritonitis or cirrhosis.

Rapid development of ascites with enlargement of the spleen and sometimes hæmatemesis suggests portal thrombosis; if symptoms pointing to cirrhosis are already present, it is probably secondary to this, and even in their absence it may be secondary to latent cirrhosis.

An examination of the circulatory system and the urine should prevent confusion between ascites due to cirrhosis and that due to heart failure or kidney disease; but these conditions may be associated together.

Treatment.—Paracentesis should be performed as soon as the accumulation of fluid causes discomfort or seriously interferes with the digestion, circulation or respiration. Hæmatemesis is a further indication, as paracentesis reduces venous engorgement. The trocar should be inserted in the middle line between the umbilicus and pubes, or in the flank. Care must be taken to avoid the liver and spleen. A trocar and tube of moderate bore should be used, as the very fine Southey's tube formerly employed tends to become blocked and the discomfort caused by the paracentesis is needlessly prolonged.

A salt-free diet should be given, as ascitic fluid never contains less than 8 grm. of sodium chloride in each litre; if the quantity of salt taken in the day is reduced to 0·8 grm., less than 100 c.c. of ascitic fluid can collect during the same period, as the urine always contains some salt, and the percentage in the body fluids never falls greatly below the normal. The quantity of salt and water retained can be still further reduced by giving 30 grains of calcium chloride three times a day.

Organic mercurial diuretics, such as mersalyl, which diminish absorption of water by the renal tubules, so increase the urinary output that the accumulation of fluid in the abdomen is much retarded. They are most effective if the patient is already on a salt-free diet and is taking calcium chloride, and if a diuretic, such as theophylline (theocin), which stimulates glomerular secretion, is given simultaneously. Ampoules containing 1 or 2 c.c. of a 10 per cent. solution of mersalyl with 5 per cent. theophylline (injection of

mersalyl, B.P.) are used. Initial doses of 0·5 c.c., 1 c.c., 2 c.c., and 3 c.c. are given intramuscularly on alternate days, after which 2 c.c. are injected weekly as long as necessary.

Diuretics are more valuable as preventatives when the fluid first appears or after it has been removed than as curatives when a large quantity is present, as the pressure on the renal veins makes the kidneys less active, and an enormous quantity of fluid has to be excreted by them before the accumulation can disappear, whereas comparatively little urine need be passed to prevent re-accumulation of ascitic fluid after tapping.

Operations devised with the object of increasing collateral circulation between the portal and the general venous system are so rarely successful and are so often followed rapidly by death that they should never be performed.

The bowels should be kept well open, but severe purging weakens the patient and is likely to aggravate the catarrh of the alimentary canal which is often already present. Epsom salts, which also promotes biliary drainage, is the most suitable aperient.

ARTHUR F. HURST.

SECTION X

DISEASES OF THE BLOOD

THE blood is sometimes regarded as the mixed secretion or product of the blood-forming organs. For the purposes of description and for the better understanding of the changes in disease, it is more convenient to think of the blood and blood-forming organs as composed of three distinct systems or tissues: (1) the red cells and their precursors, sometimes known as the erythron; (2) the white cells and the immature cells from which they arise; (3) the platelets and the megakaryocytes. These three systems of cells exist side by side in the plasma and bone-marrow, and are often affected simultaneously by disease, but they are to a large extent independent of each other. Before discussing separately the three systems of cells and their diseases, it will be convenient to say a few words about the total volume of the blood.

THE BLOOD VOLUME

The total volume of the blood is about 90 c.c. per kilogram of body weight, *i.e.* some 6000 c.c. in an average individual, or about one-eleventh of the body weight. Of this volume the cells constitute about 42 per cent., the remainder being plasma. The blood volume is moderately diminished in anæmia; it is moderately increased in the splenomegalies, in leukæmia and in erythrocytosis, and greatly increased, even to two or three times the normal, in erythræmia. There is a slight increase in œdema, due to an associated œdema of the blood, but no change in arterial hypertension. The blood volume is moderately increased in pregnancy, in order to allow for the fœtal circulation. Of great importance in practice are the conditions in which the volume of circulating blood is suddenly and considerably diminished. The chief causes are hæmorrhage and shock. In acute anæmia from hæmorrhage or blood destruction there is extreme exhaustion, faintness or syncope, air-hunger, sweating and thirst. The degree of shock depends largely on the rate of bleeding. A sudden hæmorrhage of 1500 to 2000 c.c. may be fatal, while as much as 60 per cent. of the total amount of blood may be lost without death if the hæmorrhage is prolonged over 24 hours or more. The blood count is of limited value in determining the patient's condition, inasmuch as the concentration of the blood may be unaffected in the early stages. In alimentary hæmorrhage the blood urea may be raised, owing to absorption of the effused blood, and the height of the rise is a fair measure of the severity of the bleeding. In all forms of hæmorrhage a systolic pressure below 80 mm. of mercury, a progressive increase in pulse-rate and the development of crepitations in the lungs are all serious signs.

Examples of the shock syndrome are trauma, anaphylaxis, burns, dehydration and toxæmia such as are met with in alkalosis, diabetic coma, cholera and severe infections. The patient becomes collapsed, complains of thirst, the skin is pale, cold and moist, the breathing quick and shallow, the pulse rapid and almost imperceptible, and the blood pressure low. The kidneys are inadequately supplied with blood and the output of urine may almost cease. The symptoms are often mistaken for heart failure, but there is no orthopnœa, venous engorgement, or œdema, and the symptoms are really due to loss of fluid from the circulation and stasis of blood in the capillaries.

The logical treatment in all forms of shock is to increase the blood volume and the venous return to the heart in any way possible. The foot of the patient's bed may be elevated, the legs bandaged from the ankles to the mid-thigh and the intake of fluid by the mouth increased, unless these measures are otherwise contra-indicated. The patient should be kept warm, and inhalation of oxygen or oxygen plus carbon dioxide may be helpful. Apart from sedatives for pain, drugs are of little value. Various types of infusion have been used at different times with the object of restoring the blood volume to normal and it has thus been discovered that whole blood and plasma are the ideal fluids. Solutions of saline or dextrose produce only transient improvement and, moreover, both these solutions and also gum acacia often have undesirable side effects. In shock due to hæmorrhage a transfusion of 500 c.c. of blood should be administered at once and this may be followed, if necessary, by the continuous transfusion of blood at a rate of 90 to 150 c.c. an hour until the hæmoglobin has been raised to 70 per cent. or over. In shock not due to hæmorrhage there is no reduction in the oxygen-carrying power of the blood—indeed, the concentration of hæmoglobin is usually higher than normal. In such cases it is better to give plasma or human serum rather than whole blood, as they restore the volume and normal concentration of the blood and resist diffusion from the capillaries. The amount required may vary between 200 and 1000 c.c.

THE RED BLOOD CELLS

The red blood cells are biconcave discs with a mean diameter of 7·20 microns (6·7 to 7·7 μ), a mean volume of 85 cubic microns (75 to 95 $\mu\mu$), and a mean corpuscular hæmoglobin content of 29 micromicrograms [1] (26·5 to 31·5 $\gamma\gamma$). Their size and shape are adapted to the carriage of hæmoglobin and the supply of oxygen to the tissues. The blood of a healthy young male contains about 5·5 millions of red cells per c.mm. and 16 g. of hæmoglobin per 100 c.c.; of a healthy female about 4·75 millions of red cells per c.mm. and 14 g. of hæmoglobin per 100 c.c. The normal range of variation of the erythrocyte count is from a million above to a million below the average male value, *i.e.* any figure between 4·5 and 6·3 million red cells per c.mm. may be considered normal, and there is naturally a corresponding fluctuation in the hæmoglobin percentage. A hæmoglobin percentage below 85 per cent. is always abnormal and evidence of anæmia, though symptoms rarely appear until the hæmoglobin falls below 75 per

[1] A micromicrogram is the millionth of a millionth part of a gram ($1 \text{ g.} \times 10^{-12}$), and is abbreviated by the Greek letters gamma ($\gamma\gamma$).

cent. Erythrocytes and hæmoglobin are subject to much less diurnal variation than the white cells, but significant changes may occur after exertion. For purposes of calculation the normal red cell count is taken as 5 million cells per c.mm., and the corresponding amount of hæmoglobin (14·5 g. per 100 c.c. of blood) is taken as 100 per cent. hæmoglobin. The *colour index* measures the average amount of hæmoglobin contained in the red corpuscles of a sample of blood, and is calculated from the formula

$$\text{Colour index} = \frac{\text{Hæmoglobin per cent.}}{\text{Number of red cells per cent. of the normal.}}$$

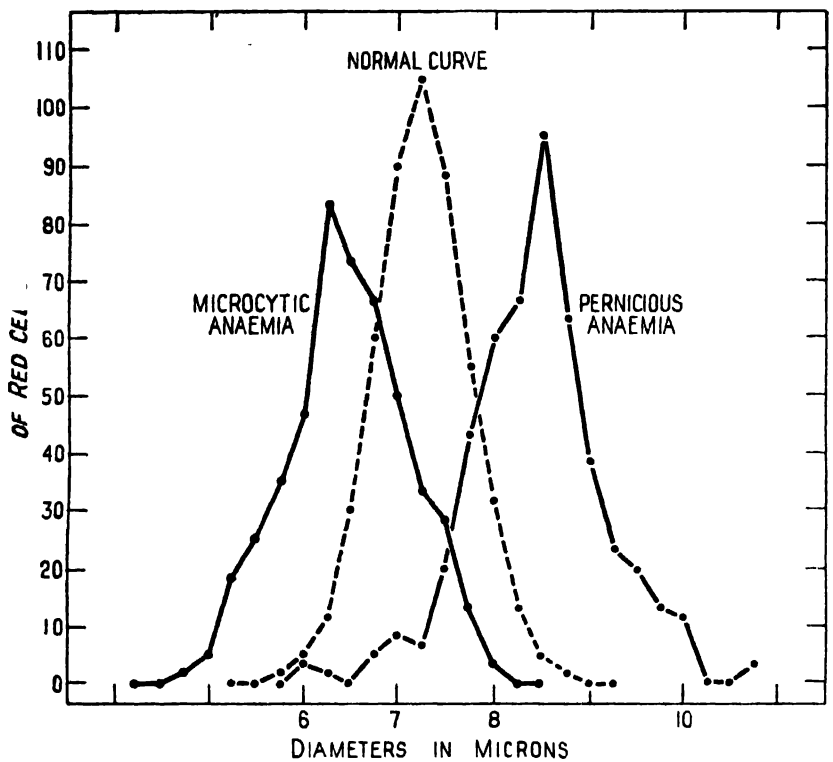

FIG. 18.—Frequency distribution curves of red cell diameters in health and disease (Price-Jones curves).

The red cells in any sample of blood are never absolutely equal, but show a certain amount of variability in size, or *anisocytosis*. The degree of variability, or anisocytosis, is often increased in anæmia and may be of diagnostic significance. The mean diameter of the red cells and their variability is determined by measuring the diameter of 500 successive red cells under the microscope on a stained thin smear. The results are then plotted on squared paper, with the number of cells counted as ordinates and the

diameter of the cells as abscissæ, to obtain what is known as a red cell diameter distribution curve, or Price-Jones curve (Fig. 18). Abnormal variability in the size of the cells will be shown by a widening of the base of the curve. Cells which are larger than normal and fall to the right of the limits determined on healthy individuals are called *megalocytes*. Small cells which fall to the left of the limits of health are called *microcytes*. A cell of normal diameter is a *normocyte*. The cell volume is obtained by centrifuging a sample of blood under standard conditions; the mean cell volume is calculated from the height of the column of red cells and the total red cell count. As the red cells age, they become malformed and finally broken into fragments which are engulfed by the phagocytic cells of the liver, the spleen and other tissues. These malformed red cells are called *poikilocytes*. In all forms of anæmia the cells put into circulation are less perfect than in health, and poikilocytosis more rapidly develops.

Blood Groups.—In the year 1900 Landsteiner and his pupils made the surprising discovery that the red cells of mankind are not immunologically identical, and that the sera of many people contain antibodies which agglutinate and destroy the red cells of others. There are, in fact, four main blood groups, which are determined by the presence or absence of two agglutinogens, A and B, of which either may be present separately (groups A and B), neither may be present (group O), or both may be present together (group AB). Corresponding to these two agglutinogens are their homologous antibodies or agglutinins—anti-A (or α) and anti-B (or β)—which are present in the serum in reciprocal relationship to the agglutinogens of the cells. The following table illustrates the Landsteiner classification of blood groups and the distribution among the population in England.

Blood Group.	Agglutinin.	Agglutinogen.	Per Cent.
AB	None (0)	A and B	3
A	β	A	42
B	α	B	9
O	α and β	None (0)	46

It can be seen that the serum of group AB will not agglutinate the red cells of any other group, and for this reason group AB has been called "universal recipient." For similar reasons members of group O are called "universal donors," because their red cells contain no agglutinogen; but blood from group O should only be transfused into members of other groups in extreme emergency, as the agglutinins in the serum of the donor may destroy the red cells of the recipient. If we wish to administer human plasma or serum, we must use either the same group or group AB. The supply of donors belonging to group AB is unfortunately small, but recently it has been suggested that plasma of this group may be prepared artificially by mixing equal parts of blood of groups A and B. By this procedure the agglutinins are absorbed on the corresponding red cells and a plasma free of agglutinins is obtained. It has been shown by a number of observers that

the blood groups have sub-groups, and interaction may occur between members of the same group. The existence of agglutinogens A_1 and A_2 is now generally accepted. For this reason the compatibility of donor and recipient must always be confirmed by direct cross-matching of the cells of the donor and the serum of the recipient. Two further agglutinogens, M and N, are recognised, but as there are no naturally occurring antibodies to these substances, they have no clinical significance and are estimated only for medico-legal or anthropological evidence.

Nomenclature.—The red cells are formed in the bone-marrow, probably within the lumen of capillary vessels which connect the sinuses to each other. The nucleated precursors are known by the generic name of *erythroblasts*. In normal marrow the erythroblasts are *normoblasts*, which subsequently develop into normocytes, but in certain diseases larger forms with more primitive nuclei are found, the *megaloblasts*, which give rise to megalocytes. The nucleated red cells lose their nuclei by extrusion or solution, but for a time they still contain remnants of the original basophil cytoplasm, which gives the red cell a bluish tinge in ordinary stained smears (*diffuse basophilia* or *polychromasia*). Certain dyes, such as brilliant cresyl blue, when brought in contact with the fresh-drawn blood, precipitate this basophil cytoplasm in a network or reticulum, and on this account these immature red cells are called *reticulocytes*. Polychromasia and reticulocytosis are identical conditions revealed by different stains. The normal reticulocyte count is ½ to 2 per cent. A similar precipitation may occur *in vivo* when poisons, such as lead, circulate in the blood stream and the reticulum becomes visible in ordinary preparations (*punctate basophilia*).

As we learn more about the so-called blood diseases, we find it increasingly difficult to classify them in a simple way, as they may be due to causes originating outside the blood stream and the bone marrow. On this account we refer to many of them by names which merely describe the type of reaction or blood picture. Thus, anæmias may be described as hæmorrhagic, hæmolytic, or aplastic in type. According as the colour index is high, normal, or low, they are described as *hyperchromic*, *orthochromic* or *hypochromic*. They can also be classified by the size of the red cells into *megalocytic*, *normocytic* and *microcytic* anæmias. These two sets of terms correspond roughly with each other, but they are not absolutely interchangeable, and each should be used strictly according to definition. As the colour index is always determined, whilst the size of the red cells is not often measured, the former set is more commonly employed.

THE SYMPTOMATIC ANÆMIAS

Synonym.—Secondary Hypochromic Anæmia.

Definition.—A symptomatic anæmia is one which arises in the course of some other well-defined disease. The colour index is usually low and hardly ever above unity. In the rare cases in which the colour index rises above unity, the disturbance of the erythropoietic tissues is usually so profound that for practical purposes all the megalocytic anæmias can be regarded as definite diseases of the erythropoietic tissues.

Ætiology.—The most obvious cause of anæmia is hæmorrhage: acute hæmorrhage occurs most commonly from trauma, bleeding from the alimentary tract, and the accidents of child-birth; chronic hæmorrhage is often due to hæmorrhoids, menorrhagia, and in tropical countries hookworm disease. Hæmolysis is a rare event, but it may be induced by chemical poisons, such as sulphanilamide and arseniuretted hydrogen, or by infection by hæmolytic organisms, such as the *Streptococcus hæmolyticus* or the *Bacillus welchii*, or by malaria. Acute infections rarely produce much anæmia, but severe anæmia may develop in protracted septic infection, acute rheumatism, rheumatoid arthritis, and other subacute or chronic infections, such as typhoid fever. In my experience focal sepsis is seldom responsible for an anæmia. Tuberculosis causes little anæmia until the later stages, when hæmorrhage, suppuration or intestinal ulceration has occurred. Syphilis also is rarely the cause of anæmia, except in the more florid stages, or from involvement of the liver, or from paroxysmal hæmoglobinuria. Malaria has already been mentioned. Of the toxæmias responsible for anæmia, nephritis and lead poisoning are the most important. Malignant disease is one of the commonest causes of anæmia; it may act in various ways—hæmorrhage from a malignant ulcer, cancerous cachexia, and invasion of the bone-marrow. Anæmia which is due to mechanical limitation of the bone-marrow by tumours or tumour-like conditions, such as leukæmia, Hodgkin's disease, infective granulomata and kala-azar, is sometimes described as myelophthisic anæmia, but this is an incorrect and unnecessary use of a word which is one of the synonyms for aplastic anæmia.

Pathology.—Two factors can be distinguished in these symptomatic anæmias. The first is loss of blood by hæmorrhage or hæmolysis. This leads to hyperplasia of the bone-marrow, and an outpouring of new red cells to repair the deficiency. The colour index is low, because hæmoglobin regeneration lags behind the restoration of a normal cell count, and the reticulocyte count is increased to 5 or 10 per cent., or higher. Chronic and repeated hæmorrhage may so exhaust the hæmatinic reserves that the body cannot repair the hæmoglobin deficiency, the anæmia remains torpid, and the reticulocyte count is low; rapid recovery occurs on the exhibition of large doses of iron. The second factor in the symptomatic anæmias is depression of the erythropoietic tissues by toxæmia. Hæmopoiesis may be inhibited without much structural alteration in the marrow, but in other cases the marrow becomes hypoplastic and may even degenerate completely. The output of new red cells is diminished, the reticulocyte count is low and the colour index a little below unity. Usually increased blood destruction and diminished blood formation are present in varying degree, and the blood picture is modified accordingly. The white cells and platelets are normal or increased in number, unless the marrow is greatly depressed. The other tissues generally show anæmia, œdema, and fatty change.

Symptoms.—The symptoms, other than those of the primary malady, depend on the speed with which the anæmia develops, and in acute anæmia from hæmorrhage or blood destruction there may be actual shock. In chronic anæmia, on the other hand, it is surprising how well the patient may feel. No complaint may be made with a hæmoglobin of 40 per cent., and only of undue fatiguability with a hæmoglobin of 20 per cent. Inquiry elicits such

symptoms as dyspnœa, palpitations, anginal pain, fainting attacks and œdema of the extremities. The pallor is best seen in the conjunctivæ or the palate; the skin is a bad guide, for it is often pale when there is no anæmia, and sunburnt and deceptively healthy when anæmia is severe. The pulse is rapid and the heart dilated, and systolic murmurs may be audible over the præcordium.

Diagnosis.—The cause of a symptomatic anæmia may be obvious, but on the other hand it may demand the most searching overhaul of the patient with all the resources of a modern hospital. Attention should be particularly focussed on the alimentary tract, as conditions such as diaphragmatic hernia, peptic ulcer, carcinoma of the stomach or bowel, polypi and hæmorrhoids may exist with no other symptom than anæmia.

Prognosis and Treatment.—The prognosis and treatment are those of the primary disease. In acute anæmia the patient should be transfused if his condition is critical. In chronic hæmorrhagic anæmia iron is of great value. In the majority of the symptomatic anæmias it is possible to produce a normal blood picture for a time by iron, liver and repeated transfusions, and so bring the patient into condition for operation or similar treatment. Apart from such emergencies, it is doubtful whether the transient benefit of a transfusion is commensurate with its risks in patients suffering from toxæmia, while iron and liver may have little effect if the cause of the anæmia is not removed. The treatment of anæmia is discussed in detail at the end of this section.

THE DEFICIENCY DYSHÆMOPOIETIC ANÆMIAS

An important group of anæmias is due to a defective supply of raw materials for blood formation. As these anæmias are the result of a disturbance in the growth of the red cells, they are called *dyshæmopoietic*. Absence of the factor which protects against pernicious anæmia (P.A. factor) gives rise to a megaloblastic reaction in the marrow and a megalocytic anæmia. The erythropoietic tissue hypertrophies and red marrow encroaches on the shaft of the long bones, but few of the cells mature or are delivered into the blood stream. Iron and traces of copper are needed for the manufacture of hæmoglobin, and when these minerals are lacking, the normoblasts do not mature and only a subnormal number of small pale cells is produced—a microcytic hypochromic anæmia. Vitamin C and thyroxine are also essential for blood formation. In their absence there is a general decline of hæmatopoiesis, rather than a specific variation from the normal. Both the latter conditions are frequently complicated by hæmorrhage and iron deficiency, but if this does not happen, hypothyroidism may produce a megalocytic anæmia which closely mimics pernicious anæmia. The dyshæmopoietic anæmias are frequently associated with glossitis, gastro-intestinal disorders and degeneration of the nervous system. The reticulocyte count is low, and the white cells and platelets are normal or diminished. Remission of the disease is attended by an outpouring of reticulocytes in numbers directly proportional to the extent of the hyperplasia of the bone-marrow. This is called the *reticulocyte crisis*.

1. NUTRITIONAL ANÆMIA OF INFANTS

Synonym.—Anæmia of Prematurity.

Anæmia of moderate degree is present in practically all infants, whether fed by the breast or artificially. It may become very severe, especially in twins and premature babies, who come into the world with a small store of iron, or after intercurrent infection, or when suckling is protracted beyond the normal period. It disappears spontaneously on the adoption of a mixed diet, and it appears to be a pure mineral deficiency, resultant from the low iron and mineral content of the milk, and reparable by inorganic salts of iron. In severe cases the hæmoglobin is reduced to 30 per cent. or less. The colour index is low. Death may occur, especially when the anæmia is exacerbated by intercurrent infection. Repair of the anæmia is followed by increased resistance to infection. Treatment is by iron and ammonium citrate, in a dosage of 4½ to 9 grs. daily. It is essential to accustom the infant to the iron slowly, as the sudden administration of the full dose may cause colic and diarrhœa. For this reason administration is started very gradually, particularly in young infants. In bottle-fed babies the solution of iron and ammonium citrate is added to the milk, or proprietary foods containing iron are used. The mother should be warned that the stools will be dark. There are few babies, whether breast-fed or bottle-fed, who are not improved by the prescription of iron.

2. IDIOPATHIC HYPOCHROMIC ANÆMIA

Synonyms.—Chlorosis and Late Chlorosis; Achylic Chloranæmia; Simple Achlorhydric Anæmia; Chronic Microcytic Anæmia of Women; Anæmia of Iron Deficiency.

Definition.—A chronic anæmia of low colour index occurring almost exclusively in women and associated frequently with glossitis and achlorhydria.

Ætiology.—This is the commonest of all the idiopathic anæmias, occurring typically in women between the ages of 20 and 50. It was formerly most prevalent in adolescent females and was known as chlorosis, or green sickness. Juvenile cases have now become rare, as a result probably of improvement in the diet, dress and environmental conditions of young females, and the incidence of idiopathic hypochromic anæmia has shifted to the later years of the reproductive epoch. A few cases are met in both sexes in childhood and in old age. It is more common in hospital than in private practice, probably because of the higher birth-rate and the poorer nutrition. The anæmia is the result of a deficient supply of iron to the blood-forming organs, which may be brought about in three ways: firstly, a diet poor in iron; secondly, impaired absorption of iron owing to achlorhydria or hypochlorhydria; thirdly, loss of iron in menstruation or pregnancy. There is no doubt that the last factor is the most important, as is shown by the facts that the complete syndrome of idiopathic hypochromic anæmia with glossitis, koilonychia, splenomegaly and microcytosis seldom occurs in the male, and that in the female the disease disappears spontaneously after the menopause. Moreover, women tend to eat less iron-containing

food than men, although they require more iron. The absorption of iron is promoted by the solvent action of the hydrochloric acid of the gastric juice and is therefore impaired in achlorhydria. An important group of cases of idiopathic hypochromic anæmia is the result of gastro-enterostomy and similar operations which neutralise or abolish the gastric secretion. The occasional appearance of idiopathic hypochromic anæmia and pernicious anæmia in different members of the same family is usually associated with a hereditary tendency to achlorhydria. Although achlorhydria may predispose to anæmia, epithelial symptoms, such as glossitis, angular stomatitis, achlorhydria and koilonychia, may be the result of iron deficiency and may occur in the absence of anæmia.

Pathology.—The bone-marrow is moderately hyperplastic, and microscopic examination shows an increased number of normoblasts. The spleen is moderately enlarged by a simple hyperplasia. The epithelium of the tongue and pharynx may show a leucoplakial degeneration. In patients with achlorhydria there is a diffuse chronic gastritis which eventually leads to atrophy of the mucous membrane of the stomach. The other organs exhibit the effects of a simple anæmia.

Symptoms.—Symptoms may first be complained of after a pregnancy, or an influenzal attack, but careful inquiry often elicits the information that the patients were always pale, or that they have previously come under medical care for anæmia. Symptoms fall into two categories. First there are those due to anæmia: general weakness, headaches, palpitation and dyspnœa; præcordial pain on exertion is common and may be of anginal severity; slight œdema of the ankles occurs, but anasarca or ascites is unusual. The second category of symptoms is composed of those due to dyspepsia, probably the result of the achlorhydria: lack of appetite, epigastric pain and distress, retching and vomiting after meals, flatulence and bilious attacks; constipation is frequent, but diarrhœa is unusual.

The facies is often pathognomonic, the sallow, wrinkled face and prematurely grey hair contrasting with the smooth, white and transparent body skin. The nails are frequently brittle and painful, and occasionally they are hollow and depressed like a spoon (koilonychia); on cure of the anæmia the new nail exhibits the normal contour and consistence. Glossitis is present in about half the cases. It is often painless and unknown to the patient, but on the other hand it may be the chief complaint. In the active stages the tongue is reddened and excoriated, and vesicles may appear and break down to form shallow ulcers. In the chronic and quiescent stages the filiform papillæ are destroyed, leaving a smooth bald tongue. The inflammation may spread to the buccal mucosa and to the corners of the mouth and lips, conditions known as angular stomatitis, perlèche or cheilosis. Passing backwards to the pharynx, the affection produces huskiness and a most troublesome dysphagia, which may be the presenting symptom (the Plummer-Vinson syndrome, see p. 546). Idiopathic hypochromic anæmia is, in my experience, much the commonest cause of the Plummer-Vinson syndrome. The spleen is palpable in less than 10 per cent. of cases of idiopathic hypochromic anæmia and is rarely greatly enlarged. The other signs are those of anæmia. There are no changes in the spinal cord, but functional nervous disorders, nervous breakdowns, aphonia, and pruritus frequently occur. The menses are more often scanty than heavy; owing to relaxation of the anæmic uterus these women

are, however, prone to postpartum hæmorrhage and to menorrhagia about the menopause.

Achlorhydria or extreme hypochlorhydria is found in about 70 per cent. of cases with the Rehfuss test meal, but stimulation with histamine shows that only about half have absolute achlorhydria. The gastric ferments are still present, although often reduced in amount. The achlorhydria is usually a permanent abnormality, preceding the anæmia and remaining when it is cured. The anæmia is of low colour index, and the red cells are usually smaller than normal. It is essentially a hæmoglobin deficiency, and often the red cell count is little below normal. The white cells and platelets are normal; an occasional normoblast may be present. Reticulocytes are within normal limits, and van den Bergh's reaction is negative. A typical count is: red cells, 3,500,000 per c.mm.; hæmoglobin, 35 per cent.; colour index, 0·5; white cells, 7000; differential count normal. In exceptional cases the red cells may fall nearly to a million and the hæmoglobin to 15 per cent. On treatment with iron there is a reticulocyte crisis, most marked in the most anæmic cases, but seldom exceeding 15 per cent., the red cells are rapidly restored to the normal number, and the hæmoglobin is more slowly regenerated. There may be a transient erythrocytosis during the recovery phase.

Complications and Sequelæ.—The Plummer-Vinson syndrome is the most important complication, occurring in about 15 per cent. of cases. The changes in the epithelium of the tongue and pharynx predispose to malignant disease, and epithelioma of the tongue and carcinoma of the hypopharynx develop in a few instances. There is a risk of transition into pernicious anæmia, most marked in women with a family history of that disease, but in my experience the risk is not great. Thrombosis is a rare complication.

Diagnosis.—Many cases are overlooked, or diagnosed as debility or functional nervous disorder, on account of the vagueness of the symptoms. Such mistakes are only to be avoided by examining the blood. Care should be taken to exclude other causes of anæmia, more especially malignant disease, and it is wise to remember that idiopathic hypochromic anæmia is very uncommon in females past the menopause, and in males of any age. The symptoms may suggest pernicious anæmia, but the low colour index and negative van den Bergh reaction are incompatible with this diagnosis, as also is the failure to respond to treatment by liver or stomach. In the rare disease aplastic anæmia the colour index is high, white cells and platelets are diminished, necrotic ulcerations occur, and there is no response to iron. If the spleen is enlarged the differentiation from splenic anæmia may present much difficulty. In splenic anæmia the spleen is greatly enlarged, there is often a history of jaundice or hæmatemesis, the skin may be pigmented and the fingers clubbed, and there are signs of liver damage, such as enlarged veins, positive van den Bergh reaction and impaired lævulose tolerance. In the absence of such symptoms the patient should first be treated with large doses of iron, when both the anæmia and the splenic enlargement will disappear if the correct diagnosis is idiopathic hypochromic anæmia.

Course and Prognosis.—The disease is chronic, and the average duration of symptoms before treatment is 5 years. It is rarely fatal, but in the

absence of proper treatment many patients remain invalids for years. There is a strong tendency to relapse, which can only be avoided by re-examination at intervals or by persisting with a small dose of iron.

Treatment.—Treatment is by large doses of iron by the mouth. Liver and stomach extracts are of no value in this disease. Transfusion is seldom necessary, and should be reserved for patients *in extremis*. Septic foci should be removed, especially from the mouth and pharynx. Factors likely to aggravate the anæmia, such as hæmorrhoids, should be dealt with appropriately. Hydrochloric acid relieves the dyspepsia, but has no action on the anæmia. Glossitis and dysphagia commonly improve when the anæmia is repaired; a simple mouth-wash may be prescribed, and Hurst's mercury tube may be passed for the dysphagia. Menorrhagia may be very troublesome; with rest in bed at the periods, large doses of calcium salts by mouth, and, if necessary, injections of cotarnine hydrochloride or hydrastinine hydrochloride, in younger subjects the condition usually subsides after a few months. After age 40 this complication is more intractable, and if it persists then, it is advisable to induce an artificial menopause by means of X-rays or operation.

3. PERNICIOUS ANÆMIA

Symptom.—Addison's Anæmia.

Definition.—A disease characterised by megalocytic anæmia, achylia, and a tendency to degeneration of the spinal cord, which pursues a remittent course, and which is invariably fatal unless appropriate treatment is instituted.

Ætiology.—The disease is most common between the ages of 40 and 60, though analysis shows that it becomes relatively more frequent in each decade. True pernicious anæmia has been observed in children, but it is very rare before the third decade. It is found in all civilised countries, though it is not very common in Jews, and it affects males and females equally. There is a hereditary proclivity, and achlorhydria without symptoms, achlorhydric dyspepsia, simple achlorhydric anæmia, pernicious anæmia and subacute combined degeneration of the spinal cord are sometimes observed in different members of the same family.

The disease is due to absence of an *intrinsic factor*, which is secreted by the pyloric segment of the stomach, the duodenum, and in diminishing degree possibly by the remainder of the intestine. It is generally held that the intrinsic factor is a ferment, which reacts with an *extrinsic factor* in the food to produce the principle which prevents pernicious anæmia (P.A. factor). Intrinsic factor is quite distinct from pepsin and rennin. The nature of the extrinsic factor is not known, but it is present in any well-balanced diet. P.A. factor is absorbed from the small intestine and stored in the liver and, to a less extent, in other organs, such as the kidney and the central nervous system. P.A. factor is essential for normal blood formation and the nutrition of the spinal cord. In its absence the bone-marrow undergoes megaloblastic degeneration, and the circulating red cells probably break down more rapidly than normal. The lesion which abolishes the secretion of intrinsic factor by the pyloro-duodenal segment practically always suppresses the secretion of hydrochloric acid and pepsin by the body of the

stomach. Achylia is therefore a cardinal symptom of pernicious anæmia; but it is important to remember that the achylia is coincidental with and not causative of the anæmia, and that owing to the secretion of intrinsic factor by the duodenum, resection of the stomach is not necessarily followed by pernicious anæmia. We do not know the nature of the lesion in pernicious anæmia which affects the rather widely distributed system of cells which secrete intrinsic factor, but probably it is often a degenerative change associated with advancing years and favoured by hereditary vulnerability. Gastro-enteritis, dysentery and similar infections, and operations on the stomach appear to be important predisposing agencies. The occasional occurrence of pernicious anæmia during pregnancy and as a result of hyperthyroidism and pituitary disease suggests that endocrine factors are sometimes at work and probably dietetic errors also are occasionally responsible.

Megalocytic anæmia similar to pernicious anæmia occurs in a number of other conditions in which nutrition or digestion is impaired. These anæmias may be classified in the following three categories: first, megalocytic anæmia due to a defective diet; second, megalocytic anæmia due to defective absorption of anti-anæmic factors when the intestines are diseased; and third, megalocytic anæmia due to defective storage or metabolism of anti-anæmic factors, as when the liver is extensively damaged. The gastric juice may be perfectly normal in such conditions, and for some unexplained reason subacute combined degeneration of the spinal cord is much less frequent than in pernicious anæmia. In all these anæmias the red cells show anisocytosis and megalocytosis, and the bone-marrow shows megaloblastic degeneration comparable with the findings in Addison's anæmia. Recent research has nevertheless indicated that there are a number of subtle differences in the blood pictures and in the response to treatment, and though the whole group responds to the injection of crude liver extract, some of them are refractory to treatment by the more highly purified liver extracts now available. It is possible that liver contains a number of related hæmopoietic principles, rather than a single P.A. factor.

(*a*) *Nutritional macrocytic anæmia.*—Megalocytic anæmia due to defective diet is uncommon in temperate zones except in fanatical vegetarians, but very common in tropical and subtropical countries where large populations subsist on famine diets. The attack is usually precipitated by an extra factor, such as pregnancy or malaria, and hæmolysis may be much more evident than in pernicious anæmia.

(*b*) *Stenosis, resection or ulceration of the small intestine.*—These conditions probably act by interfering with the absorption of the P.A. factor.

(*c*) *Intestinal parasites.*—The most important is Bothriocephalus latus. The mode of action is unknown, but is probably an interference with absorption.

(*d*) *Sprue.*—Megalocytic anæmia is almost the rule in sprue. It is in part due to the intestinal disease, but in the majority of cases the gastric secretion is also impaired.

(*e*) *Fatty diarrhœa.*—In fatty diarrhœa, such as occurs in cœliac disease, idiopathic steatorrhœa, pancreatic disease, gastro-colic fistula and extensive operations on the alimentary tract, megalocytic anæmia from interference with absorption of P.A. factor is occasionally observed, though not so constantly as in sprue.

(*f*) *Disease of liver.*—Megalocytic anæmia with normal gastric secretion is occasionally observed in cirrhosis and other diffuse diseases of the liver. It is attributed to inability to store pernicious anæmia factor in the liver, but it may be noted that the anæmia of hepatic cirrhosis rarely responds to treatment in the same satisfactory way as other deficiency dyshæmopoietic anæmias.

Pathology.—The remainder of this section deals with true pernicious anæmia, though similar changes are observed in the other megalocytic anæmias just mentioned. The body may not be wasted, the fat is a peculiar yellowish colour and the muscles reddish-brown. All the tissues are anæmic, and the heart muscle shows fatty degeneration. Free iron is present in the liver, the kidneys and other tissues. The bone-marrow is hyperplastic, like red currant jelly, but usually there are some areas of aplasia; microscopic examination shows many megaloblasts, and in addition endothelial cells containing phagocyted red cells and their débris. Degeneration of the postero-lateral columns of the spinal cord is present in about 80 per cent. of cases. The stomach shows a diffuse atrophic gastritis.

Symptoms.—Patients with pernicious anæmia are not infrequently well built, with broad faces, short deep chests and wide sub-costal angles; the hair is often prematurely grey, and the skin may be pigmented. Its incidence in persons of this type was first noted by Addison, whose description of the symptoms remains unsurpassed. "The disease makes its approach in so slow and insidious a manner that the patient can hardly fix a date to his earliest feeling of that languor which is shortly to become so extreme. The countenance gets pale, the whites of the eyes become pearly, the general frame flabby rather than wasted; the pulse perhaps large, but remarkably soft and compressible, and occasionally with a slight jerk, especially under the slightest excitement; there is an increasing indisposition to exertion, with an uncomfortable feeling of faintness or breathlessness on attempting it; the heart is readily made to palpitate; the whole surface of the body presents a blanched, smooth and waxy appearance; the lips, gums and tongue seem bloodless; the flabbiness of the solids increases; the appetite fails; extreme languor and faintness supervene, breathlessness and palpitations being produced by the most trifling exertion or emotion; some slight œdema is probably perceived about the ankles; the debility becomes extreme, the patient can no longer rise from his bed, the mind occasionally wanders, he falls into a prostrate and half-torpid state, and at length expires; nevertheless, to the very last and after a sickness of perhaps several months' duration, the bulkiness of the general frame and the amount of obesity often present a most striking contrast to the failure and exhaustion observable in every other respect."

A lemon-yellow colour of the skin was common in the days before liver therapy was introduced, but now that patients come under effective treatment early it is rarely seen. The same is true of splenomegaly, which requires considerable time for its development and is now found in only about 5 per cent. of untreated patients. The temperature may be slightly raised. Angina may occur from impoverishment of the blood supplied to the heart. The liver may be enlarged. The urine contains much urobilin and often a trace of albumin. Alimentary symptoms constitute an important chapter of the disease. Glossitis of the type described in idiopathic hypochromic anæmia occurs in

over 50 per cent. of cases, but curiously enough there is no tendency to involvement of the pharynx, or to dysphagia. It may precede the anæmia by some years. Achlorhydria is an invariable symptom, and pepsin is greatly reduced or absent. Achlorhydria has many times been demonstrated before the onset of the anæmia, and it persists when the blood has been repaired. Dyspepsia is frequently present, with flatulence, ill-defined generalised abdominal pain, soft bowel movements and recurrent attacks of diarrhœa. The dyspepsia is partly due to the achlorhydria, but it is greatly aggravated by the anæmia, and in the critical periods of the disease the pain and vomiting may be so troublesome as to prevent effective medication by mouth. If the trouble persists after repair of the anæmia, disease of the gall-bladder should be suspected. Nervous symptoms, due to subacute combined degeneration of the spinal cord, are an integral part of the disease, but for convenience they are described elsewhere (p. 1738). Mental symptoms appear in a small percentage of cases; they are usually delusions of persecution, and the patient swears that he is being poisoned by his relatives or his physician. Exceptionally such patients become stuporose and die in coma, even though their anæmia is not profound.

The cardinal feature of the blood picture is megalocytosis. By the time the patient seeks medical advice the red cells are often less than 2 millions per c.mm., and counts of the order of half a million have occasionally been obtained. Hæmoglobin is not reduced to the same extent as the red corpuscles and the colour index is above unity. Such complications as hæmorrhage may lower the colour index, but megalocytosis persists. The mean diameter of the red cells averages about 8·3 microns; there is much anisocytosis and poikilocytosis. Reticulocytes are within normal limits except during a remission, spontaneous or induced. Normoblasts and megaloblasts are often present, more especially in the agonal stages of the disease and also on the inception of very active treatment; they are rarely present in mild cases, and their diagnostic importance has been greatly overestimated. The serum is brownish-yellow, and the indirect van den Bergh reaction is positive. The white cells are reduced in number, an average count being about 4000; the decrease is chiefly due to diminution in the granulocytes and the monocytes. The neutrophil cells are of an old type, many having 5 or more lobes to their nucleus, and occasional giant neutrophils and myelocytes are present. Platelets are scanty.

Complications and Sequelæ.—Complications are infrequent, for subacute combined degeneration is one of the elements of the disease and not truly a complication. It is doubtful whether pernicious anæmia ever terminates in aplastic anæmia, and most reports of this sequel can be attributed to errors of diagnosis or to incomplete examination of the marrow after death; arsenic may have produced aplasia of the marrow in rare cases before liver was introduced into treatment. Gout and venous thrombosis occasionally occur, especially during intensive treatment. The gall bladder is diseased in about 25 per cent. of cases. It has been suggested that patients with pernicious anæmia are abnormally prone to carcinoma of the stomach, but the evidence is not statistically convincing. Intercurrent infection, whether from diminished resistance on account of the anæmia, or from the trophic or bladder lesions of spinal paralysis, is a very dangerous event.

Course.—In young subjects the disease may run an acute course, with

fever and purpura, and prove fatal after a short illness. Such a course is unusual, for remissions are one of the most constant features of the disease. The commonest number is two, but there may be five or six; their duration is about six months. The patient may feel perfectly well during a remission, but the blood rarely becomes quite normal. The untreated disease is usually fatal in one to three years, though exceptional cases may live much longer, as the result of an unusual remission. One of the patients at Guy's Hospital first came under treatment at age 30 for dyspepsia; at age 41 he was re-admitted for typical pernicious anæmia, with high colour index and megaloblasts, which responded to treatment by arsenic; he remained well till age 64, when he was readmitted to hospital for relapse of the pernicious anæmia of ten months' duration; he had complete achlorhydria; the anæmia responded to treatment with liver. The cause of the remissions is uncertain, but is probably a partial recovery of the secretion of intrinsic factor.

Diagnosis.—The disease is often suggested by the triad of symptoms, glossitis, anæmia and acroparæsthesia. It is confirmed by the blood picture, more especially the megalocytosis and anisocytosis, the absence of reticulocytosis, and the presence of hyperbilirubinæmia. In doubtful cases a test meal should be performed, for free hydrochloric acid in the gastric juice for all practical purposes rules out the diagnosis. Marrow obtained by sternal puncture or biopsy shows the pathognomonic megaloblastic degeneration. The megalocytic anæmias of nutritional and alimentary disease which closely resemble pernicious anæmia have already been discussed. An important differential diagnosis is from carcinoma of the stomach. In this disease the fæces contain occult blood, and the anæmia is usually of a hypochromic type. In a few cases the two diseases coexist, the pernicious anæmia being the result of a cancerous gastritis and achylia, or cancer developing in the stomach of a patient who already has pernicious anæmia. Aplastic anæmia may be mistaken for pernicious anæmia, but there is less anisocytosis and megalocytosis, van den Bergh's reaction is negative, free hydrochloric acid is frequently present in the gastric juice and liver treatment is unsuccessful. The rare diseases aleukæmic leukæmia and chronic hæmolytic anæmia can usually be differentiated by careful analysis of the symptoms and the blood. In the absence of complicating infection, anæmia which does not respond to liver treatment in effective dosage is very unlikely to be pernicious anæmia.

Prognosis.—The underlying deficiency is for all practical purposes incurable, but with thorough and persistent substitution therapy both the anæmia and the spinal symptoms can be completely arrested, and there is no reason why the patient should not live the normal span.

Treatment.—Treatment is by liver or stomach, as described at the end of the chapter (p. 821). I cannot too strongly emphasise the necessity of keeping the blood at a level of 5 million red cells per c.mm., and 100 per cent. of hæmoglobin if nervous and infectious complications are to be avoided. Many patients have a delusive sense of well-being with a blood count as low as 3 million red cells per c.mm., and 60 per cent. hæmoglobin, but at this level the degeneration of the nervous system may continue to advance. It is, therefore, essential to examine the blood at regular intervals. Even with a normal blood count, acroparæsthesia or increase of the nervous symptoms demands a larger dosage of effective substance. After all, it is

impossible to give an overdose. In patients who are profoundly anæmic transfusion may be necessary, but in view of its dangers it should, wherever possible, be withheld in favour of injections of liver extract. Hydrochloric acid may be advisable for the dyspeptic symptoms, but it is rarely necessary. Iron deficiency and hypothyroidism are occasional complications of pernicious anæmia. They should be suspected especially in patients in whom it is difficult to bring the blood completely back to normal, and they should be corrected by appropriate doses of iron or thyroid. Arsenic and intestinal antiseptics are to be avoided. Septic foci should be removed, though the operation should be postponed until the anæmia is under control.

On instituting successful treatment in a patient with pernicious anæmia there is a reticulocyte crisis, which reaches its maximum between the tenth and fourteenth days with oral therapy, and between the third and the seventh days with parenteral therapy. The peak is directly proportional to the severity of the anæmia, and values of 30 to 40 per cent. are by no means uncommon. The blood and the general condition of the patient are gradually restored to normal, glossitis becomes quiescent, and the surface of the tongue may be reclothed with filiform papillæ. The nervous symptoms improve more slowly, and gross spastic paralysis is unlikely to be repaired. Nevertheless the degree of improvement may be surprising. In more than one bedridden case I have felt I was doing the patient little service in curing his anæmia, but after months of careful treatment, massage and re-education, the patient has successively discarded his wheel-chair, his crutches and his sticks, and has returned to active employment.

LEUCO-ERYTHROBLASTIC ANÆMIA

Synonyms.—Osteosclerotic Anæmia; Myelophthisic Anæmia; Leukanæmia.

Leuco-erythroblastic anæmia is uncommon. It is found in association with certain diseases of the bones or bone-marrow, and is characterised by the presence in the peripheral blood of unusually immature red cells and a few immature white cells. It is described here rather than with the symptomatic anæmias because the disturbance of blood formation is so profound as to suggest an affinity with the dyshæmopoietic anæmias. The anæmia is characterised clinically not by its severity but by the number of cells in the peripheral blood that normally are confined to the marrow as precursors of the red and white cells of the blood. The colour index is commonly a little below unity and the mean diameter of the red cells usually within normal limits. Reticulocytes are constantly above normal and nucleated red cells are present, often in large numbers. The leucocyte count is commonly normal or only a little raised, but occasionally very high values may be observed, even above 100,000 per c.mm. There is always an excess of myelocytes and on many occasions myeloblasts are also present. The platelet count is usually low. The van den Bergh reaction is usually negative, unless complications are present. The spleen may be palpable, either as a result of myeloid metaplasia or more rarely from neoplastic infiltration. The anæmia is presumably due to irritation or disturbance in the maturation of the hæmopoietic tissues by the bony disease. It does not respond to iron or liver, and transfusion is the only effective treatment. Leuco-erythroblastic

anæmia has been observed in the following conditions, but in some of them it is the exception rather than the rule. In the adult, at any rate, malignant disease is much the most important cause of leuco-erythroblastic anæmia.

1. Erythroblastic Anæmia of Cooley [Thalassæmia or Mediterranean Anæmia].—This disease is practically confined to children of Mediterranean stock, and is characterised by numerous immature erythrocytes in the peripheral blood, mongoloid facies, splenomegaly and generalised bony changes due to hypertrophy of the marrow tissue. It is a hereditary condition which manifests itself soon after birth, and life is rarely prolonged past childhood. The bony dystrophy is similar to osteitis fibrosa, but pathological fractures are not common and symptoms come principally from the anæmia, which is severe and ultimately fatal. X-ray examination shows widening of the medullary portion of the bones, erosion and thinning of the cortex, and a peculiar fuzzy outline of the skull often compared to hair standing on end.

2. Marble-Bone Disease of Albers-Schonberg.—This is a congenital disease characterised by increased density of the bones, spontaneous fractures, splenomegaly, and anæmia which is often of the leuco-erythroblastic type. Symptoms usually begin in childhood with fractures following trivial injury and general backwardness. The anæmia is mainly due to narrowing of the marrow cavity from progressive broadening of the cortex and the X-ray appearances are pathognomonic.

3. Myelosclerosis.—In this bony dystrophy of unknown ætiology there is an excess of bone or fibrous tissue in the spongiosa and medullary cavity of the bones without any appreciable alterations in the corticalis or tendency to fracture. It is a disease of adult life. The only complaint is of the anæmia and there are no symptoms referable to the bones. The differential diagnosis from leukæmia may offer the greatest difficulty, though X-ray examination and biopsy of the skeleton may be of assistance.

4. Carcinomatosis of Bone.—As already emphasised, this is the most important cause of this type of anæmia. Symptoms of the primary growth may be elicited, and X-ray examination will usually reveal the metastases in the skeleton. It is often stated that growths of the thyroid and the prostate are especially liable to metastasise in the bones, but growths of the breast, stomach and lungs are more common causes of leuco-erythroblastic anæmia, owing presumably to their greater frequency.

5. Multiple Myeloma.—Only a small percentage of cases of multiple myeloma are accompanied by leuco-erythroblastic anæmia (p. 1390).

6. Leukæmia and Other Conditions.—In rare instances of leukæmia large numbers of reticulocytes and nucleated red cells may appear in the circulating blood as a result, presumably, of the leukæmic deposits in the bone-marrow. This phenomenon has sometimes been described as "mixed leukæmia" when myelocytes and erythroblasts appear in a case of lymphatic leukæmia, or as "leukanæmia" when the disturbance of erythropoiesis is prominent, but it is now believed to be a manifestation of the leuco-erythroblastic process. Numerous immature red and white blood cells may very rarely appear in the blood in the course of miliary tuberculosis, syphilis and Hodgkin's disease. The evidence suggests that in all such cases the bone marrow is involved and the blood disorder is of the leuco-erythroblastic type, but owing to their great rarity, their pathology has not yet been satisfactorily worked out.

APLASTIC ANÆMIA

Synonym.—Panmyelopathy.

Definition.—Aplastic anæmia is produced by aplasia of the bone-marrow, which results in reduction or total failure of blood regeneration. Usually all three elements in the bone-marrow—erythropoietic tissue, leucopoietic tissue and megakaryocytes—are simultaneously involved. Rare cases occur in which there is a pure lesion of one of these tissues, and not infrequently one of them is predominantly affected. The term *aplastic anæmia* is applied more particularly to cases in which the erythropoietic tissue is especially damaged. Aplasia of the leucopoietic tissues is described later under the title *agranulocytosis*, and aplasia of the megakaryocytes under the title *malignant thrombocytopenia*.

Ætiology.—The disease occurs at all ages and in both sexes. In a number of cases the aplasia of the bone-marrow is due to destruction by a well-recognised poison: 1. X-rays, radium and thorium; the latter two are most dangerous when they are taken into the body and produce persistent internal radiation. 2. Benzole and many of its derivatives, such as arseno-benzol, dinitrophenol, trinitrotoluene and the sulphonamides. 3. Mercury, silver and gold, the last of course being now widely used in the treatment of rheumatism and tuberculosis. 4. Acute infections, such as measles, scarlatina, diphtheria and typhoid; these causes are more potent in childhood. In a large proportion of cases no noxious agency can be traced and it is possible that many are due to an idiosyncrasy to substances not normally regarded as harmful, a phenomenon we have already learnt to recognise in amidopyrine agranulocytosis and sedormid purpura.

Pathology.—A variety of changes may be found in the marrow in refractory anæmias which have been regarded as aplastic during life. In the classical aplastic anæmia the marrow is hypocellular or acellular. An actual excess of erythropoietic tissue may be found in radium poisoning and in the rare *achrestic anæmia* which is believed to be due to inability of the marrow to utilise P.A. factor. In other cases the changes resemble leukæmia, Hodgkin's disease, or myelosclerosis, though no other organs are involved. Necrotic ulcers are commonly found in the mouth and more rarely in the bowel. The liver, spleen and lymph-glands show no gross change, but microscopically there is usually some hæmosiderosis of the liver and spleen, attributable both to the absorption of extravasated blood and to the breakdown of transfused red cells.

Symptoms.—It is possible to distinguish acute and chronic forms of aplastic anæmia, and it is clear that the degree of aplasia or hypoplasia of the marrow varies in different patients and probably at different times in the same patient. In one of my cases, which subsequently came to autopsy, the onset was abrupt, with jaundice and high fever. More common initial symptoms are hæmorrhage from the thrombocytopenia, and necrotic ulcerations from the leukopenia. Cases which begin acutely are liable to run a rapid course and terminate fatally in a few weeks or months. In chronic cases the presenting symptom is more likely to be anæmia and the disease may pursue a remittent course. Physical examination is commonly negative except for the anæmia and such complications as purpura and ulceration. There are

no specific alimentary or nervous symptoms, and the spleen and lymph glands do not enlarge. The blood picture is characterised by a decrease of all the cells, erythrocytes, leucocytes and platelets; the absence of immature white cells and nucleated red cells; and the lack of signs of reaction, such as hypochromia, anisocytosis and reticulocytosis. By the time a blood count is done the red cells have often fallen to about 1·5 million per c.mm. and the colour index is about unity. Van den Bergh's reaction is negative. The white cells are about 3000 or 4000 per c.mm., usually falling below 2000 before death; the diminution is chiefly due to the small number of polymorphonuclear cells. In chronic cases a very considerable degree of megalocytosis may develop, and so long as the colour index remains high and the leucocyte count low, the disease cannot be regarded as cured.

Diagnosis.—Acute cases are commonly mistaken for an infectious process and it should therefore be the rule to examine the blood in all cases of severe oral or faucial infection. Chronic cases are more often confused with pernicious anæmia, but do not respond to liver. Essential thrombocytopenia may be suggested by the low platelet count and the hæmorrhagic tendency, but is excluded by the leucopenia and the non-regeneratory character of the anæmia. Aleukæmic leukæmia offers most difficulty. The absence of enlargement of the lymph-glands, liver, or spleen, however, should differentiate aplastic anæmia from this disease. In doubtful cases a sternal marrow puncture or biopsy should be performed.

Prognosis and Treatment.—In all cases enquiry should be made for exposure to toxic substances. No very adequate statistics are available for prognosis, as aplastic anæmia has only recently been properly separated from other grave anæmias. It was formerly considered hopeless. Some patients recover outright and others continue without need of treatment for a number of years, but the seriousness of the illness should not be minimised. Probably the response to transfusion is the best guide. The blood should be brought approximately to normal by a rapid series of transfusions, or by a continuous transfusion of two or three litres of blood. If it is then possible to maintain a normal count by transfusions at intervals of two or three weeks, there is good hope that the bone-marrow may gradually regain its hæmopoietic function. But too often it is found that the transfused blood is lost by hæmorrhage or is quickly and mysteriously destroyed. However well the patient appears clinically, the prognosis should be guarded as long as the blood picture is abnormal, for such patients are always liable to sudden deterioration from infection or an acute hæmolytic reaction. Iron, liver and similar remedies are of little value.

THE HÆMOLYTIC ANÆMIAS

In discussing the symptomatic anæmias, I have mentioned the occasional development of anæmia from hæmolysis of the corpuscles by micro-organisms, bacterial toxins and other poisons. There is also evidence that excessive hæmolysis plays a part in the pathology of the megalocytic anæmias due to deficiency of hæmopoietic principles. There now remains for discussion a group of hæmolytic anæmias which are relatively uncommon and of which

the most important examples, acholuric jaundice, sickle-cell anæmia and the grave familial jaundice of infants, are due to congenital anomalies in the blood-forming organs. Before treating these diseases individually, it will be convenient to describe the characteristics which are common to all the hæmolytic anæmias. If a great many red cells are broken down in a short time, there are hæmoglobinuria and jaundice, but in chronic hæmolytic anæmia it is sometimes surprising how slight is the jaundice. The colour index varies according to the mode of reaction of the bone-marrow, but it is usually round about unity and there may be frank megalocytosis. Owing to the vigorous attempts of the bone-marrow to repair the anæmia, the reticulocyte count is high, and nucleated red cells and even megaloblasts appear in the peripheral blood. In chronic hæmolytic anæmia the white cells are unaffected or a little diminished. When hæmolysis is acute and rapid, there is a leucocytosis, during which very immature white cells may appear in the peripheral blood; the platelets first fall and later rise above their normal level. Apart from the hæmolysis, which gives rise to anæmia, enlargement of the liver, spleen, and occasionally the lymph-glands, hyperplasia of the bone-marrow and hæmosiderosis, there are no signs of systemic disease and the alimentary and nervous systems are normal.

1. ACHOLURIC JAUNDICE

Synonyms.—Spherocytosis; Congenital Hæmolytic Anæmia (type Chauffard-Minkowski).

This disease, which is due to congenital abnormality of the red corpuscles, and is characterised by increased fragility of the cells, a variable degree of jaundice and anæmia, splenomegaly, and a strong tendency to the formation of gall-stones, is described elsewhere (page 689).

2. SICKLE-CELLED ANÆMIA

Synonym.—Drepanocytosis.

Definition.—A severe anæmia, characterised by the appearance in the blood of a number of red blood corpuscles of a peculiar sickle shape.

Ætiology and Pathology.—Up to the present the disease has been observed only in the negro. It is hereditary and familial, behaving as a Mendelian dominant. In the affected families some members who have sickle cells in their blood do not suffer from anæmia. The disease usually dates from infancy. Of its essential cause, nothing is known. The post-mortem appearances do not throw any light upon the pathology.

Symptoms.—The patients are obviously anæmic, and the sclerotics exhibit a greenish-yellow tinge. The liver is bulky, but the spleen is not enlarged. The disease is characterised by intermittent paroxysms of fever, up to 103° or 104°, with severe stabbing pains in the muscles and joints, which last for two or three weeks. In the intervals the patients suffer but little, though they are listless and depressed. The red blood corpuscles in the intervals reach a number of about 3,000,000 per c.mm., but during the paroxysms they rapidly fall to less than half that number. The white cells are usually about 15,000 per c.mm., but may rise to as much as 40,000. The sickle-shaped corpuscles vary in numbers. They appear to increase in

number on a warm slide. The coagulation-time, the bleeding-time, the fragility of the corpuscles, and the numbers of platelets are all within normal limits.

Course and Prognosis.—The course of the disease is slow but progressive, and death usually occurs before the age of thirty.

Treatment.—Up to the present time, no treatment has appeared materially to influence the progress of the disease, and splenectomy is of no value.

3. OVALOCYTOSIS

In rare cases the red cells are elliptical, instead of being circular. This again is a familial abnormality, inherited as a Mendelian dominant, but it is not certain that it predisposes to anæmia.

4. FAMILIAL ICTERUS GRAVIS NEONATORUM

This is a familial disease in which successive infants in the same family become jaundiced within a few hours to a day after birth, though the first-born often escapes. The children become progressively anæmic, pass into a drowsy condition, and usually die in a few days or weeks. At its onset the disease resembles physiological jaundice. During intra-uterine life the red cells circulate in higher concentration than after birth, to compensate for the poor supply of oxygen from the placenta. It is probable that physiological jaundice results from the hæmolysis of superfluous corpuscles on the inception of pulmonary respiration, and that grave familial jaundice is a morbid exaggeration of this process. It is now recognised that grave familial jaundice is the most important manifestation of a pathological state known as *Erythroblastosis Foetalis*, which may affect several children of the same parents and appear in rather different guises. In *congenital hydrops* the child is still-born or dies a few hours after birth; the placenta is enlarged, the vernix caseosa is often a deep yellow colour, the body is dropsical and the blood anæmic. In *congenital anæmia of the newly-born*, on the other hand, the disease is less acute than in familial jaundice, there is little or no jaundice, but there is severe hyperchromic anæmia with numerous immature red cells in the blood, and enlargement of the liver and spleen. Post-mortem examination in all forms of erythroblastosis fœtalis usually shows much extra-medullary hæmopoiesis and considerable deposition of iron in the viscera. It is still not certain whether erythroblastosis foetalis is a hæmolytic anæmia, as suggested here, or whether it may not be a dyshæmopoietic anæmia due to a failure in the normal development of the red cells. The diagnosis is suggested by the family history, the large placenta and the golden vernix caseosa, and is confirmed by the discovery of an abnormal number of nucleated red cells in the blood smear. Treatment must be prompt, owing to the rapid progress of the anæmia and the deleterious effect of the jaundice which at this early age may produce degenerative changes in the central nervous system. Either 30 to 50 c.c. of blood should be given by transfusion, or 5 to 10 c.c. of the mother's serum should be injected intramuscularly daily. If given in time this treatment arrests hæmolysis and a complete and lasting recovery takes place.

5. ACUTE HÆMOLYTIC ANÆMIA OF LEDERER

Synonym.—Acute Febrile Anæmia.

Lederer's anæmia occurs most commonly in the first two decades of life, though cases have been observed at every age. The onset is acute, with fever, slight rigor, headache, lassitude and vomiting. Jaundice of more or less intensity appears early, though as a rule the patient is more anæmic than icteric. In the most acute cases there is hæmoglobinuria. A variety of symptoms may occur as a result of thromboses or infarcts in various organs. The red count may fall in a few days to a million cells per c.mm.; the red cells are usually normal in size and resistance, and the colour index is about unity. There is a reticulocytosis, often with many nucleated red cells. The white count is usually raised and occasionally there is a remarkable leucocytosis, with an outpouring of myelocytes and even myeloblasts in the circulating blood. The cause of the sudden breakdown of the red cells is unknown; it is not due to any recognised infection. The disease ends in death, or recovery within a period usually of two to six weeks. The differential diagnosis is from other forms of hæmoglobinuria (see p. 1292), from infections such as septicæmia, and from acute leukæmia. The mortality of the untreated disease is high. Treatment is by transfusion, repeated if necessary until the hæmolytic process appears to have been arrested. The results of such treatment are good and recovery once established is permanent.

6. HÆMOLYTIC ANÆMIA WITH RECURRENT HÆMOGLOBINURIA

Synonyms.—Nocturnal Hæmoglobinuria; Hæmosiderinuria; Chronic Hæmolytic Anæmia (type Marchiafava-Micheli).

A rare chronic disease characterised by paroxysms of hæmoglobinuria, which commonly occur at night, and persistent hæmolytic anæmia. It is a disease of adult life and affects both sexes. The spleen is usually enlarged though not to the same degree as in acholuric jaundice. The disease is differentiated from acholuric jaundice by the normal size, shape and fragility of the red cells, and the occurrence of hæmoglobinuria; and from the paroxysmal hæmoglobinuria of syphilis by the negative Wassermann reaction, absence of relation to exposure to cold, and persistence of anæmia between the paroxysms. There is no curative treatment; splenectomy has little effect and the disease usually leads to death after a few years.

7. CHRONIC ACQUIRED HÆMOLYTIC ANÆMIA

Synonym.—Hæmolytic Anæmia (type Hayem-Widal).

Chronic hæmolytic anæmias are occasionally encountered which are difficult to fit into any of the foregoing categories. Acholuric jaundice, like other hereditary diseases, does not always run true to type, and many of these cases are undoubtedly sporadic and atypical examples of acholuric jaundice. Others are probably larval or atypical forms of hæmolytic anæmia (type Marchiafava-Micheli) in which the hæmolytic process is not of sufficient

intensity to produce hæmoglobinuria. Syphilis and Hodgkin's disease may occasionally produce a hæmolytic anæmia; a Wassermann reaction should therefore be performed and careful search made for enlarged lymph glands. Leuco-erythroblastic anæmia must also be excluded. Iron and parenteral liver should be given a fair trial, as a deficiency dyshæmopoietic anæmia may occasionally simulate a hæmolytic process, more especially when complications such as intestinal ulceration are present. If the spleen is enlarged and anæmia persists after investigation and treatment on these lines, splenectomy should be advised, though improvement cannot be promised with the same confidence as in straightforward familial acholuric jaundice. Transfusion may be necessary to make the patient fit for operation; but it is sometimes followed by severe reactions in hæmolytic anæmia, and it is wise therefore to begin with a small " pilot " transfusion.

ANÆMIA IN PREGNANCY

The *physiological anæmia of pregnancy* is due to dilution of the blood in pregnancy owing to altered circulatory conditions and increased blood volume. The hæmoglobin rarely falls much below 75 per cent. in healthy women, the colour index is unity, and there is no hypochromia or poikilocytosis. It often gives rise to unnecessary anxiety. It is distinguished from pernicious anæmia by its mildness and from iron-deficiency anæmia by the normal colour index. It requires no treatment. The same circulatory phenomena are likely to aggravate *idiopathic hypochromic anæmia in pregnancy*, and in women who have suffered from anæmia in a previous pregnancy or who are unable to take an optimal diet, it is wise to prescribe iron as a prophylactic throughout the period of gestation and lactation. Megalocytic or hyperchromic anæmia is very rare in pregnant women in this country, though it is common in tropical or sub-tropical zones. The condition may have different causes, and the prognosis differs accordingly. The following causes of megalocytic anæmia in pregnancy have been differentiated.

1. *Nutritional macrocytic anæmia* is much aggravated by pregnancy, and then assumes a frankly megalocytic type.

2. Pregnancy may occur in a patient with *pernicious anæmia*, or pernicious anæmia may first begin in pregnancy, persisting after gestation; achylia gastrica is present, and subacute combined degeneration may develop.

3. Pernicious anæmia may occur as a temporary phenomenon during pregnancy, disappearing after gestation. The secretion of free hydrochloric acid may be normal, but there is evidence that the hæmatinic ferments are depressed, presumably as a result of the pregnancy. Subacute combined degeneration does not occur. The disease responds well to treatment by liver or stomach. It may or may not recur in subsequent pregnancies. This is the true *pernicious anæmia of pregnancy*, and it is very rare.

Hæmolytic anæmias, which should be separable from pernicious and allied anæmias by the Price-Jones curve and the reticulocytosis, also occur in pregnancy. Most frequently they result from infection by hæmolytic streptococci in the puerperium. It is also probable that the hæmolytic anæmia of Lederer occurs in pregnancy.

ANÆMIA IN CHILDHOOD

Anæmia in children is more difficult to classify than in adults, not merely because of the difficulty of making detailed studies of the blood and the other systems, but also because of the great lability of the blood-forming organs of children. A condition which in an adult induces a mild secondary anæmia, with slight leucocytosis and perhaps an occasional normoblast, in a child may induce profound anæmia, with the appearance of myelocytes and even myeloblasts and megaloblasts in the circulating blood; the spleen and the liver are more often enlarged. Both on this account and on account also of the small blood volume, anæmia is a more urgent disease in the child than in the adult; hæmorrhage is ill-tolerated, and a moderate nutritional anæmia may be fatally aggravated by a trivial intercurrent infection. Treatment should therefore be prompt, and it is often wise to give a transfusion of 50 to 200 c.c. of blood to tide over the interval before medical treatment can take effect. For similar reasons the results of treatment are often better in the child than the adult, and aplastic conditions of the bone-marrow which are almost inevitably fatal in the adult may be repaired in the child. Apart from certain rare congenital anæmias, the causes of anæmia in childhood are identical with those in later life, and with careful clinical and hæmatological examination, supplemented if necessary by the van den Bergh reaction, the fragility test and the Price-Jones curve, a satisfactory diagnosis should usually be obtained. In this way the vague titles formerly used, such as anæmia mitis and gravis, and pseudo-leukæmia, are gradually being replaced by more exact diagnoses.

Symptomatic Anæmia is little different from the same condition in the adult. Hæmorrhagic anæmia is rather unusual in childhood, while causes more peculiar to this age are cyclical vomiting, diphtheria, pyelitis and acute rheumatism. Anæmia may also be secondary to diseases of the blood-forming organs, such as splenic anæmia and Hodgkin's disease. Any type of anæmia in childhood may be complicated by infection, when very bizarre leukæmoid blood pictures may result. Cases characterised by the rapid development of anæmia, jaundice and hæmoglobinuria at one time appeared in epidemics among new-born children in hospitals and institutions (Winckel's disease), but they have practically disappeared with the introduction of antiseptic methods. They were probably due to infection by streptococci or hæmolytic colon bacilli, and sporadic cases still occur as a result of umbilical sepsis.

Dyshæmopoietic Anæmia.—There is a group of mild hypochromic anæmias in childhood which link the nutritional anæmia of infancy with the idiopathic hypochromic anæmia of later life. The condition has been described as *anæmia mitis* or *chlorotic anæmia of childhood*, but it is essentially due to errors of diet and impaired digestion. Treatment is by large doses of iron, and is very successful. Severe anæmia may occur in the course of cœliac disease, and in occasional instances it is of a megalocytic type and requires liver for its treatment; the anæmia may dominate the clinical picture and the fatty diarrhœa be overlooked. True pernicious anæmia rarely, if ever, occurs in childhood.

Aplastic Anæmia is by no means uncommon in childhood, occurring with

special frequency at the age of 12 or 13. It may be of any of the types described in the adult, and is sometimes known as *anæmia gravis*. The prognosis is bad, though perhaps less hopeless than in the adult.

Anæmia pseudo-leukæmica infantum is the term applied by von Jaksch to a group of cases of severe anæmia in children under 3 years of age, most frequent between 6 and 20 months. It is a disease of the poorer classes, and among them it has become uncommon in recent years. The onset of the disease is insidious, with increasing pallor and irregular fever. The abdomen is protuberant, owing to the size of the spleen, which often reaches the iliac crest and the middle line of the belly; the organ is hard, smooth and free from tenderness. The liver and superficial lymph-glands may be slightly enlarged, and purpura and hæmorrhage may occur. The erythrocytes are diminished to 2,500,000 or 3,000,000 per c.mm., and show some slight alteration in shape and size. Nucleated cells are always present—sometimes in large numbers. The hæmoglobin shows a decrease to from 20 to 40 per cent. of the normal, so that the colour index is low, from 0·5 to 0·7. There is nearly always a leucocytosis at some time during the course of the disease, but it is moderate, rarely reaching above 30,000, and sometimes the number may sink as low as 5,000. The feature of the blood films is the constant presence of myelocytes, which occur in numbers greatly above those found in any other disease except leukæmia, though seldom in numbers sufficient to suggest that disease. Not infrequently there is evidence of excessive blood destruction. It is now held that the syndrome described by von Jaksch is not a single disease-entity, but that it includes various types of anæmia of congenital, nutritional, or infectious origin, modified by the peculiar lability of the blood-forming organs in childhood. If gross lesions, such as leuco-erythroblastic anæmia, acholuric jaundice and splenic anæmia are not present, the prognosis is generally good; the anæmia is completely repaired and the spleen can no longer be palpated. Death may, however, occur from intercurrent maladies, such as acute diarrhœa or broncho-pneumonia.

It is obviously important to remove the cause when this can be ascertained, and malnutrition, rickets, tuberculosis and syphilis should receive their appropriate treatment. Iron and liver are usually of great service, and transfusion is indicated when the anæmia is severe. For the rest, every effort should be made to improve the diet and the general hygienic conditions. The patients do best with abundance of fresh air and light, and if possible should be nursed in the open air. Splenectomy is contra-indicated.

POLYCYTHÆMIA

Polycythæmia is a condition in which there is an increased number of erythrocytes per unit of circulating blood. It may be due to known causes, when it is called secondary polycythæmia, or *erythrocytosis*; or it may be an independent disease of the blood-forming organs, when it is called polycythæmia vera, or *erythræmia*. The following causes of erythrocytosis are known:

1. Concentration of the circulating blood, such as occurs in the dehydration of choleraic diarrhœa.

2. Diminution of the oxygen tension in the circulating blood or tissues.

Examples of this are—(*a*) residence at high altitudes; (*b*) cardiac diseases with cyanosis, especially congenital pulmonary stenosis and acquired sclerosis of the pulmonary arteries (Ayerza's disease, or cardiacos negros); (*c*) condi, tions interfering with normal pulmonary ventilation, such as emphysema-asthma, fibrosis and neoplasms of the lungs.

3. Chronic poisoning by a number of chemical agents, such as arsenic, phosphorus, carbon monoxide and aniline derivatives.

4. Cirrhosis of the liver, tuberculosis of the spleen, and similar conditions associated with splenomegaly or portal stasis, in rare instances.

5. A transient erythrocytosis may occur in the stage of recovery from anæmia.

These causes should always be excluded before diagnosing polycythæmia vera; in doubtful cases estimation of the blood volume is helpful, for polycythæmia vera should not be diagnosed unless the blood volume is considerably increased.

1. Polycythæmia Vera.

Synonyms.—Erythræmia; Splenomegalic Polycythæmia; Osler-Vaquez Disease.

Definition.—A disease characterised by well-marked and persistent increase in the number of red corpuscles due to an excessive erythroblastic activity of the bone-marrow.

Ætiology.—Erythræmia occurs more commonly in males in middle or later life, and in some studies there is evidence that it is especially prevalent among Jews born in eastern Europe. A recent theory is that erythræmia is related to Buerger's disease and is caused by sclerosis of the vessels supplying the bone marrow, so that anoxæmia develops and stimulates erythrogenesis. Familial cases of polycythæmia occur; they tend to be mild.

Pathology.—The marrow of most of the shafts of the long bones is converted into active red marrow. The spleen is enlarged and engorged, and often contains thrombotic infarcts. The liver is congested, but no anatomical change is present in it.

Symptoms.—Early symptoms are nervousness, headache, digestive disturbances and hæmorrhage from the distended vessels. The nervous symptoms take the form of lack of concentration, headaches, vertigo, or paræsthesiæ, on account of which the patient may be regarded as suffering from neurasthenia or hyperpiesia. Sometimes temporary disturbances of vision, aphasia or paralyses occur, which recover completely in a few hours. The patients are usually spare, with fair complexion and thin, often narrow, faces. There is cyanosis of the exposed surfaces, especially the cheeks, the tip of the nose and the ears. The colour varies with the temperature, being scarlet in a warm atmosphere and dark blue in the cold. The eyeballs are often bloodshot, the conjunctivæ deep red, the retinal vessels engorged and tortuous, the discs a little swollen. The spleen is palpable in three-quarters of the cases; it rarely extends beyond the umbilicus and varies in size, shrinking after a hæmorrhage or successful treatment. The liver is palpable in about one-half the cases. The urine may contain a little albumin. The blood contains from 7 to 14 million red corpuscles per c.mm., and the hæmoglobin may reach 200 per cent. The red cells are usually smaller than

normal, and the colour index is less than unity. The white cells are normal or moderately increased by a polymorphonuclear leucocytosis. In a few cases many myelocytes appear, as if there were a combination of erythræmia and leukæmia (erythro-leukæmia). The reticulocytes and the platelets are normal.

Complications.—The most important complications are vascular, and result from the increased volume and viscosity of the blood and its sluggish flow. It is noteworthy, however, that hypertension is no more common than in normal individuals in the same age-groups. Not uncommonly there are massive hæmorrhages, especially from the stomach, but also from the nose, lungs, bowel, uterus and bladder, or internally. Thrombosis is not infrequent, and in the cerebral vessels or the portal vein its consequences may be grave. It is rare for a case to progress any length of time without symptoms of peripheral arterial disease. In the beginning these take the form of acro-paræsthesia and vasomotor disturbances of a dilator (erythromelalgia), or spastic type (Raynaud's syndrome). Later, intermittent claudication and gangrene may follow. Peptic ulcer is probably a little commoner than in normal people. When the illness runs a long course leukæmia, myelosclerosis, purpura hæmorrhagica and anæmia may supervene, but it is not clear whether these conditions are the effect of the primary malady or of prolonged depression therapy.

Course and Prognosis.—The disease is very chronic, and sometimes it may exhibit long remissions. Life may be cut short by one of the vascular accidents or by infection, but many cases live to an advanced age.

Treatment.—Venesection relieves the symptoms, but its effects are temporary. The blood may be used for transfusion, and in hospital practice these patients are useful as donors. Phenylhydrazine is the most popular remedy. It destroys the excess of blood, and great care must be taken to avoid over-dosage. The dose is 1½ to 5 grains every other day until the count approaches normal; it should then be possible to find a dosage which will maintain a normal blood count, 2 grains a week frequently being sufficient. Some patients have been made dangerously anæmic as a result of incorrect diagnosis, overdosage with phenylhydrazine, or lack of supervision during treatment; jaundice, thrombosis, and necrosis of the liver and kidneys have also been observed. If phenylhydrazine produces gastro-intestinal disturbance, acetylphenylhydrazine may be tolerated; it is given in the same dosage. Arsenic is often effective if prescribed in high dosage (p. 822). X-ray treatment may also be used, though it is much slower and less certain in effect than in leukæmia. The rays should be applied over the long bones and the chest. This form of treatment is especially to be recommended when the white count is high, and in elderly patients who do not tolerate phenylhydrazine. Splenectomy is contra-indicated.

2. Methæmoglobinæmia and Sulphæmoglobinæmia

Synonym.—Enterogenous cyanosis.

Definition.—A condition characterised by cyanosis without cardiac or pulmonary lesions, associated with the presence of methæmoglobin or sulphæmoglobin in the circulating red cells.

Ætiology.—In the vast majority of cases the condition is due to the

use of drugs, especially aniline derivatives, and it has become much more common since the introduction of the sulphonamide group. Other drugs which have been incriminated are acetanilide, phenacetin, antipyrine, trional, sulphonal, potassium chlorate, and nitrites. Methæmoglobinæmia is produced by the direct action of the chemical or a breakdown product of it on the red cells. In sulphæmoglobinæmia the chemical sensitises the red cells, so that the hæmoglobin combines with hydrogen sulphide absorbed from the intestine. Sulphæmoglobinæmia is therefore much more likely to develop in constipated patients. A common sequence of events is: constipation; headaches; the use of headache powders which contain phenacetin or acetanilide; and sulphæmoglobinæmia. In very rare cases methæmoglobinæmia occurs spontaneously, apparently as a result of excess production and undue absorption of nitrites from the gastro-intestinal tract; this condition is known as *enterogenous cyanosis*. Equally rare is a familial form of methæmoglobinæmia attributed to an inborn error of metabolism—*familial idiopathic methæmoglobinæmia*. Chronic methæmoglobinæmia and sulphæmoglobinæmia are more common in women than men, and should always arouse suspicion of drug addiction, hysteria or malingering.

Symptoms.—The degree of cyanosis is sometimes out of proportion to the amount of methæmoglobin or sulphæmoglobin present, and it is probably aggravated through absorption by the red cells of coloured derivatives of the drugs themselves. The colour varies from a slight muddiness of the complexion to a deep blue. In marked cases the appearance of the patient is indeed ghastly, and yet it is belied by the comfortable general condition, the absence of any respiratory distress, and the extreme rarity of a fatal issue. In acute cases there may be no symptoms. In chronic cases the patient complains of weakness, nervousness, vertigo or fainting attacks, palpitation, headache and constipation. The blood may show a slight polycythæmia.

Prognosis.—In patients who are anæmic or who have to work at a high altitude, the condition may encroach dangerously on the reserve of functioning hæmoglobin. In other respects it is harmless.

Diagnosis.—The diagnosis depends on the spectroscopic examination of the blood for methæmoglobin or sulphæmoglobin. The brown colour of the blood can often be recognised with the naked eye. Methæmoglobinæmia, in which the altered hæmoglobin is within the corpuscles, must be distinguished from methæmalbuminæmia, in which altered hæmoglobin is present in the plasma; in the latter, there is no cyanosis, and the patient may be jaundiced. The use of drugs should always be suspected, especially in chronic and apparently inexplicable cases in women. It is surprising how skilfully they deceive their attendants and escape detection. I have known more than one woman who has lived many months in hospital and has been shown at medical meetings as a rare and mysterious case when all the time the symptoms were being produced by a bottle of phenacetin tablets concealed in the locker.

Treatment.—Recovery occurs spontaneously in 24 to 72 hours after the drug is discontinued. The cyanosis can be promptly relieved by the intravenous injection of methylene blue, 1 or 2 mg. per kilo, but it will return again if the offending drug is continued. It can be prevented, however, by the continuous administration of methylene blue by mouth, grains 1 or 2 four-hourly. Articles of diet and purgatives containing sulphur should be

avoided in patients under treatment by drugs likely to cause sulphæmoglobinæmia.

LEUCOCYTOSIS

It is important to be familiar with the normal fluctuations of the white cells. In healthy individuals the total number of white cells may vary from 3500 to 12,500 per c.mm., the average being 7500. A typical differential count is: neutrophils 66 per cent., eosinophils 2·5 per cent., basophils 0·5 per cent., lymphocytes 24 per cent., monocytes 7 per cent.; but there are great physiological variations which are best illustrated by the absolute values of the different cells. The total number of neutrophils may vary from about 1500 to 10,000; eosinophils from 0 to 1000; basophils from 0 to 500; lymphocytes from 600 to 4000; and monocytes from 0 to 1750. The total white count is at a minimum or basal level when the subject is at rest in the morning; activity, mental or physical, increases it by 60 or 100 per cent.; in addition there are rhythmical fluctuations in the number of polymorphonuclears, lymphocytes and monocytes, which are probably associated with the replacement of dead or emigrated cells. It is unwise to draw far-reaching conclusions from a single count of the white cells, and the test should always be repeated when an anomalous result is obtained, or when it is uncertain whether the figures fall within normal limits. The most obvious task of the white cells is to protect the body from attack and invasion by bacteria or similar agencies. They may be compared with a standing army which performs no useful service in times of peace, but which possesses great reserves which may be mobilised in time of war. We might press the analogy further and compare the three main groups of blood cells, the granulocytes, the lymphocytes and the monocytes, with the different fighting branches, for just as different types of warfare require different arms, so the three main groups of blood cells show independent variations in the various phases of an infection, and respond differently to different kinds of disease. An increase in the neutrophil leucocytes should strictly be called neutrophil leucocytosis or neutrophilia, but when the term leucocytosis is used without qualification it is taken to mean a neutrophil leucocytosis. Leucocytosis occurs physiologically during the later stages of pregnancy and for about a week after delivery; in the newly born infant; and after exercise, as many as 35,000 cells per c.mm. having been found after violent exertion. The causes of pathological leucocytosis are:

1. Hæmorrhage, or trauma in which tissues are injured and blood is extravasated.
2. Acute infections, especially by the pyogenic cocci.
3. Acute intoxications, such as diabetic coma, uræmia, gout, lead colic, coal-gas poisoning, and poisoning by a number of organic and inorganic substances.
4. Malignant disease, especially when the tumour grows rapidly, or involves the alimentary tract or the bone-marrow, and some cases of Hodgkin's disease.

The number of white cells in these conditions commonly varies from 12,000 to 40,000 per c.mm., according to the acuteness of the infection or intoxication, and the patient's ability to respond; in exceptional cases

the count may even exceed 100,000. The neutrophils are less mature than normal, or are altered by the toxæmia, so that many of the cells have only one or two lobes to their nuclei—a phenomenon described as the "shift to the left." In profound infections in which the patient's resistance is overcome there may be no increase in the total number of white cells but a considerable shift to the left is present; this is a sign of very ill omen. When there is a considerable leucocytosis, as in pneumonia and scarlet fever, small numbers of myelocytes may appear in the peripheral blood.

EOSINOPHILIA

The function of the eosinophil cells is not known, though it is suggested that they protect the body against the absorption of foreign proteins or of abnormal products of protein metabolism. Their number is increased by certain drugs, such as emetine, and also by feeding with whole liver. There is a rare condition of *hereditary eosinophilia* which sometimes manifests itself in different members of a family, and in which the normal proportion of eosinophils and neutrophils is reversed; in such cases infection is attended by a neutrophil leucocytosis and a temporary diminution of the eosinophilia. A constitutional tendency of the same kind is probably present in a number of individuals, and explains the high eosinophilia that may sometimes appear from trivial or unusual causes. In the symptomatic eosinophilias tabulated below it is rare for the total white count to be much increased, or for the eosinophils to exceed 20 per cent., but occasionally they may constitute over 50 per cent. of a total white count of 50,000 to 100,000. The eosinophils are usually increased in:

1. Infestation by parasites, especially hydatid cysts, ancylostomiasis and trichiniasis. *Loeffler's syndrome*, a condition in children in which transient pulmonary infiltrations are associated with blood eosinophilia, has been ascribed to the migration of larvæ of ascaris lumbricoides through the lungs.
2. Convalescence from acute diseases; they are diminished in the acute stage, except in cases of scarlatina in which there is a slight eosinophilia at the time of the eruption, and sometimes in acute rheumatism.
3. Allergic states, such as asthma and hay fever.
4. In many skin diseases.
5. In Hodgkin's disease in about one-quarter of the cases, but rarely to a high degree; and in rare cases of malignant growths, more especially when the peritoneum is involved.
6. In myeloid leukæmia and erythræmia.

Eosinophilia with Splenomegaly.

Synonym.—Eosinophilic Leukæmia.

This is an uncommon syndrome in which enlargement of the spleen is associated with persistent eosinophilia; the liver and the lymph-glands may also be palpable. The total white count is usually between 10,000 and 25,000, but it may exceed 50,000 cells per c.mm.; eosinophils constitute from 20 to 80 per cent., the majority being mature and only a small fraction myelocytes. Anæmia, if present, is of moderate degree. Post mortem the hyperplastic

bone-marrow is seen to be filled with eosinophils in all stages of development. Eosinophil cells are present in the other organs, especially the spleen and the lymph-glands, but here they are mainly adult cells. Areas of hæmorrhage and fibrosis may be found in the spleen and the lungs, and granulomatous tumours have also been observed. The benign course of the disease in many instances, the absence of anæmia, and the small percentage of myelocytes in the blood and tissues are arguments against regarding the condition as a true eosinophilic leukæmia. It is probably not a disease entity, but a syndrome of varied ætiology. Some cases are examples of hereditary eosinophilia in its severer form; others are acquired on the basis of asthma and bronchitis, syphilis, malaria, hepatic cirrhosis, myeloid leukæmia, Hodgkin's disease and other known causes; and a few cases remain obscure. The prognosis is moderately good, but death may occur from intercurrent infection. Splenectomy is contra-indicated, as it aggravates the eosinophilia. Great improvement follows anti-syphilitic treatment in cases with a positive Wassermann reaction.

LYMPHOCYTOSIS

Little is known about the function of the lymphocytes, though they are believed to play an important part in the protection of the mucosæ and the defence of the body from chronic disease. They are increased by exposure to ultra-violet light, and diminished by excessive X-radiation and by vitamin deficiency. Lymphocytes are more numerous in the blood of children than of adults, constituting from 40 to 60 per cent. of a total count of 7000 to 9000 white cells per c.mm., and their reactions to disease are much greater in early life. There are few infections in childhood which may not now and again be associated with an extraordinarily high lymphocyte count. The lymphocytes are especially increased in whooping-cough, chicken-pox, small-pox, typhus, malaria, and most constantly in glandular fever (acute mononucleosis). In isolated instances of these various infections the lymphocytes may rise as high as 75 per cent. or more of a total count of 100,000 white cells per c.mm., and leukæmia may be suspected. Usually the absence of anæmia should quiet this suspicion. The lymphocytes are moderately increased in the stage of healing of acute infections, and in tuberculosis which is progressing favourably. They are diminished in miliary tuberculosis and lesions of the lymphoid tissues, such as glandular tuberculosis, Hodgkin's disease, carcinoma and lymphosarcoma.

MONOCYTOSIS

The monocytes have only been differentiated from the lymphocytes in recent years, and not much is known about their behaviour in disease. They are increased during and after the crisis in acute infections, and also in active tuberculosis, sympathetic ophthalmia and undulant fever. Very high counts are occasionally obtained in miliary tuberculosis and infective endocarditis.

BASOPHILIA

The basophils are moderately increased in a number of diseases of the blood-forming organs, such as leukæmia, erythræmia and acholuric jaundice. The

increase of basophil cells in myeloid leukæmia is sometimes of diagnostic importance, as it may be the only abnormality present during a remission.

LEUCOPENIA

The strict meaning of the word "leucopenia" is a diminution in the total white cell count, but as the granulocytes are chiefly diminished in leucopenia, the word is often used to mean a diminution in the granulocytes. In the interests of accuracy it is better to use the terms *granulocytopenia* or *neutropenia* to indicate a diminution in the number of granulocytes or neutrophils respectively. While the majority of infections induce a leucocytosis, it is characteristic of certain diseases that the white count is normal or diminished. The most important infections in which there is leucopenia are the enteric fevers, undulant fever, influenza and measles. Leucopenia may also occur in septic infections when the resistance is overwhelmed by the severity of the infection; it is nevertheless unusual for the white blood count to sink to the low levels characteristic of agranulocytosis, and a total white count below 2500 should arouse the suspicion of an underlying abnormality in the blood-forming organs. Leucopenia resulting from septic infections differs from agranulocytosis in the presence of septic foci, positive blood cultures, and at autopsy the septic type of splenitis. As might be expected, leucopenia occurs in cachectic and debilitated states and in diseases of the blood-forming organs in which the leucopoietic tissues are depressed. There is a temporary fall in the number of leucocytes in the peripheral blood in anaphylactic shock and similar conditions, owing to the collection of the cells in the internal organs.

In the conditions already discussed the leucopenia is usually moderate in degree and produces no obvious clinical effects, the symptoms being those of the primary disorder. Leucopenia of a much more severe degree occurs in aplastic anæmia and leucopenic leukæmia. The bacteria which are constantly present on the surfaces of the body are then able to invade the tissues, and the trivial infections to which all of us are exposed take on a malignant character. The most common invaders are Vincent's organisms, with the production of fetid ulceration in the mouth and throat or elsewhere. Lesions such as cancrum oris, noma and putrid sore throat rarely develop unless the white blood cells are depressed. Such extreme leucopenia is nearly always accompanied by signs of damage to the other hæmopoietic tissues, such as anæmia and a tendency to bleed. The leucopenia is indeed only one manifestation of a general depression of marrow function. There are, however, cases in which the lesion is strictly confined to the white cells and the leucopoietic tissues, so that the red cells and platelets remain intact. It is to cases of this last type that the term *agranulocytosis* should strictly be confined, as they form a clinical entity with characteristic pathological changes, but the term is often loosely applied to any condition in which the white cell count is greatly depressed and necrotic ulceration is present.

AGRANULOCYTOSIS

Synonyms. — Malignant Neutropenia; Primary Granulocytopenia; Agranulocytic Angina.

Definition.—A disease characterised pathologically by profound leucopenia due to arrest in the development of the granulocytes, and clinically by an acute febrile illness, necrotic ulcerations and a high mortality.

Ætiology.—The majority of cases are due to an idiosyncratic reaction to drugs, especially amidopyrine and the sulphonamide group. The effect is to arrest the maturation of myeloblasts into myelocytes and polynuclear cells. Patients who have an idiosyncrasy to amidopyrine may become sensitive to the drug after taking quite a small quantity, and in the sensitised subject a dose as small as 0·2 g. may be followed by an abrupt diminution in the white cells and changes in the marrow. Agranulocytosis therefore occurs typically in patients who are taking amidopyrine in small doses or at long intervals. When a patient has taken a total of 50 g. amidopyrine with impunity (in divided doses of course) it becomes progressively less likely that he will become sensitive, though there can be no absolute surety of safety. The position with the sulphonamides is different. Agranulocytosis from the sulphonamide group rarely occurs until at least 30 g. of the drug has been taken. It is therefore infrequent before the tenth day and is more likely to be found with second or later courses of treatment. Agranulocytic syndromes may also occur after most of the poisons mentioned under aplastic anæmia (p. 785), but they are rarely so clear-cut and tend to be complicated by anæmia and hæmorrhage. Chronic and recurrent types of agranulocytosis are occasionally met with, especially in females, for which no explanation can be found. There is also a very rare disease, *hypoleukia splenica* or *primary splenic granulocytopenic leucopenia*, in which chronic agranulocytosis occurs in association with splenomegaly, without cirrhosis or drug and bacterial idiosyncrasies, and is completely relieved by splenectomy.

Pathology.—Necrotic, ulcerative or gangrenous lesions are present, most constantly in the mouth and pharynx, but they may affect any part of the alimentary canal, the rectum and in women, the vagina. Œdematous or brawny swellings may be present about the teeth, the neck, in the subcutaneous tissues, or elsewhere. The bone-marrow contains its normal complement of megakaryocytes, and erythropoiesis is normal, but granular leucocytes and myelocytes are absent; in cases dying early, small islands of myeloblasts are seen, but in the later stages these too may disappear and the only white cells seen in the marrow are focal accumulations of lymphocytes.

Symptoms.—In cases due to amidopyrine, there is often a long history of mental or physical over-exertion, followed by chronic fatigue, loss of weight and vague pains in the limbs. If the blood is examined in this prodromal phase, leucopenia of moderate degree will be found. Acute symptoms are often precipitated by dental extraction or an influenzal attack. The onset is abrupt, sometimes with rigors, and the patient complains of aching pains in the limbs and sore throat, and is rapidly prostrated. The temperature is high, ranging from 100° to 105° F. In the majority of cases ulcero-membranous lesions soon appear on the tonsils and gums, and the cervical glands may be enlarged, with surrounding brawny induration. As already indicated, other mucous surfaces may be involved, and in rare cases the sole infective lesion may be a mild redness of the throat without any other tissue or blood infection. The patient is pale but not anæmic. The liver and the spleen may be palpable, and jaundice is an occasional complication. As the disease advances the usual symptoms of a profound toxæmia appear. Examination of the

blood at this stage shows a total white count below 2000, often only a few hundred cells per c.mm.; the reduction affects especially the granulocytes, which may be diminished to about 5 per cent. or even completely absent.

Diagnosis.—Cases arising in the course of another illness which has been treated by amidopyrine or one of the sulphonamides may be very difficult to recognise. The diagnosis depends chiefly on the history and the blood picture. Specific inquiry should be made as to the use of amidopyrine, which is contained in many analgesic and hypnotic preparations, and sulphonamides, which are now very extensively prescribed. I have seen several cases in which the amidopyrine hypothesis had been discarded, but further questions revealed the fact that the drug had indeed been used or was still being used. Aplastic anæmia and leukæmia can be excluded by the blood picture, as the red cells and platelets are not affected in agranulocytosis, and there are no primitive white cells such as appear in acute leukæmia.

Course and Prognosis.—Spontaneous recovery from an acute attack may occur, but the mortality of untreated cases is about 75 per cent. In the fulminating type the patient succumbs in two or three days. In the usual acute type death or recovery occurs within a few weeks. In patients who have recovered from an acute attack and in cases where the disease has been recognised before the onset of acute symptoms, the leucocytes gradually return to a normal level if no more drug is taken; it may be six months before the normal figure is reached. The duration of sensitivity to amidopyrine and sulphonamides is not known—it may be life-long—and patients who have had symptoms of agranulocytosis should never use the drugs again.

PROPHYLACTIC.—No one should ever be given a prescription which allows amidopyrine to be taken without close medical supervision. If drugs of the sulphonamide group are given for more than a week, the blood should be examined at frequent intervals. The occurrence of drug fever 7 to 10 days after beginning sulphonamide treatment may herald the onset of agranulocytosis. Sudden deterioration in the condition of a patient who is being treated with amidopyrine or sulphonamide should always suggest a white blood cell count.

Treatment.—Treatment is disappointing; hence the importance of careful supervision of patients who are taking amidopyrine and sulphonamides, and their immediate prohibition in agranulocytosis. The remedy most commonly used is pentose nucleotide (pentnucleotide), 10 to 50 c.c. of which are injected intramuscularly every day; it often causes troublesome reactions, such as præcordial distress, rigors and fever. Liver extract may be tried in a dosage of 4 to 5 c.c. intramuscularly daily. Other remedies which have been used are neoarsphenamine injections, stimulating doses of X-rays to the bones, and transfusion, but there is no convincing evidence that they are efficacious. For local treatment the mouth may be sprayed with a saturated solution of potassium chlorate, and ulcerated areas then swabbed with a solution of copper sulphate, 10 grains to an ounce of water. Abscesses and areas of cellulitis should be drained but only essential surgery should be done. General treatment suitable to an acute febrile illness should not be neglected. In the chronic cases in which there is leucopenia but no fever or infection a ten-day course of pentose nucleotide, 20 c.c. intramuscularly daily, may be given once a month until the white count is stabilised at a normal level. A long holiday by the sea or in the mountains, away from crowded centres of

infection, is the ideal prescription. If this cannot be procured the effects of ultra-violet irradiation may be tried. The diet should be rich in vitamins and in purin foods. Teeth may be scaled and cleaned, nasal sinuses treated by postural drainage, and pyelitis treated by mandelic acid; but dental extractions and the radical extirpation of septic foci should be postponed until the white count is stabilised at a normal level.

LEUKÆMIA

Synonym.—Leukosis.

Definition.—Leukæmia is a morbid condition characterised by widespread hyperplasia of the leucopoietic tissues, either myeloid or lymphatic, which is usually associated with qualitative and quantitative changes in the white cells of the circulating blood.

Ætiology.—The ætiology is unknown, and the disease appears to occupy an intermediate position between the reaction to infections and noxious agencies on the one hand and the true neoplasms on the other. Leukæmia occurs in the lower animals also, and (like the sarcomata of these animals) it is sometimes transmissible by cell-free filtrates. In its more acute forms in man it often resembles an infection, and very similar changes in the blood and the blood-forming organs may sometimes be produced by infections and similar clearly apprehended agencies; it is difficult, however, to reconcile the tumour-like growths which sometimes develop in leukæmia with a hypothesis of infection. It differs from the ordinary neoplasms in being a system-disease, and affecting the whole organ simultaneously. The neoplastic hypothesis presents fewer difficulties, the diffuse character of the lesion being explained by the labile character of the leucopoietic tissues and being paralleled by the diffuse carcinomas of the breast and the cirrhotic liver. In experimental animals leukæmia has been induced by indole, benzole and tar, and in man it has been thought to be unduly frequent in those whose work exposes them to benzol, X-rays and radium. There is much similarity between leukæmia and erythræmia, and at times the two diseases appear to occur simultaneously, an erythro-leukæmia. Heredity is not known to play any part in the incidence of leukæmia. In a few instances the disease has followed injuries to the bones.

Classification.—We might expect to find forms of leukæmia corresponding to each of the different types of white blood cell, and classify them accordingly. In practice it is found that the only forms of leukæmia which occur at all frequently are those which involve predominantly the neutrophils and their precursors, or myeloid leukæmia, and those which involve the lymphocytes, or lymphatic leukæmia. Eosinophilic leukæmia has already been discussed; in exceptional cases of myeloid leukæmia basophil cells may predominate. Monocytic leukæmia has recently attracted much interest, but many cases so described are actually myeloblastic leukæmia, and in the majority, at any rate, myeloblasts or myelocytes as well as monocytes are present in the blood and tissues. In cases in which monocytes predominate, the leukæmia is usually acute or subacute, with fever, severe anæmia and necrotic mouth lesions, and a tendency to temporary remissions and aleukæmic phases. In leukæmia the immaturity of the cells is just as important

as the type of cell present, and for clinical work the leukæmias are therefore described as chronic myeloid leukæmia, chronic lymphatic leukæmia, and acute leukæmia. Whichever strain of cells is affected, the disease breeds true, and the two groups of cells are never involved simultaneously. Confusion has sometimes arisen owing to the ease with which very immature cells of the myeloid series, the myeloblasts, can be mistaken for lymphocytes. In acute leukæmia the cells may be so very immature that it is impossible to determine their origin, but the clinical features of acute lymphatic and acute myeloid leukæmia are identical.

1. Chronic Myeloid Leukæmia.

Synonyms.—Myelocytic Leukæmia; Spleno-Medullary Leukæmia; Chronic Leukæmic Myelosis.

Ætiology.—The disease is more common in males, who make up 60 per cent. of the cases. It is very rare before puberty, and more than half the cases begin between 30 and 50, the greatest incidence being between 35 and 45.

Pathology.—The changes which are found in the body are almost confined to the hæmopoietic organs. The bone-marrow is firm and fleshy, pale pink or grey in colour, rarely of a greenish hue. The predominant cell is the myelocyte, but there are also large numbers of myeloblasts and nucleated red cells. The spleen is usually enormously enlarged, but its outline is preserved; its surface is smooth, its consistence firm, its colour on section a greyish-red, usually mottled with infarcts. Microscopically the Malpighian corpuscles are obliterated, and the pulp is filled with myeloid cells and resembles the bone-marrow. The liver is large, firm, and of a pale yellow tint, and its capillaries contain large numbers of myelocytes. The other organs may show anæmia, hæmorrhages, and infiltration with myelocytes.

Symptoms.—Early symptoms are easy fatigue, slight loss of weight and strength, and gastro-intestinal disturbances, but the patient may first complain of the enlargement of the abdomen due to the increasing size of the spleen. The anæmia at this time is not marked, indeed the appearance is not seldom one of good health. Pain in the left side is sometimes felt, either as a result of the dragging weight of the enlarged spleen or from perisplenitis over an infarct. The average duration of symptoms before medical advice is sought is about a year. Fever is commonly slight, and there are often long periods of normal temperature interrupted now and then by small rises of short duration to 101° F. or 103° F. The basal metabolic rate is increased. Tenderness is often present over the sternum, more marked during exacerbations of the disease.

On examination the striking feature is the size of the spleen. It occupies the greater part of the left side of the abdomen, often reaching to the iliac crest below the middle line at the umbilicus. It forms a hard smooth tumour, with rounded edges, not tender to palpation and easily recognised by the characteristic notches in the anterior margin. The size tends to vary in the course of the disease, often leading to false hopes as to the efficacy of treatment. Sudden enlargement is due to hæmorrhage or infarction, and marked diminution nearly always occurs with the approach of death. The liver is larger than normal, and smooth. The lymph-glands are rarely palpable, except sometimes near the end. Impairment of vision may occur

from leucocytic accumulations or hæmorrhages in the retina, while involvement of the inner ear may lead to deafness and Ménière's syndrome.

In the later stages the anæmia becomes severe and cachexia develops. Ascites and œdema make their appearance, the heart weakens, and the patient becomes emaciated. Hæmorrhage is frequent, but rarely lethal. Death occurs from exhaustion or from intercurrent infection. It should be noted that infection may produce a temporary improvement in the blood picture, but such a remission is often followed by an aggravation of the disease, which then pursues an acute and rapidly fatal course. Conversion of chronic into acute leukæmia may also happen spontaneously.

The Blood.—The principal characteristics are progressive loss of hæmoglobin and of red cells, and increase, frequently enormous, of the leucocytes. The white count ranges from 100,000 to 1,000,000 cells per c.mm., values about 400,000 being most usual. The increase is mainly composed of cells of the granulocyte series. The typical cell is the neutrophil myelocyte, which constitutes 20 to 40 per cent. of the total; but the neutrophil, eosinophil and basophil polymorphonuclears are also increased, eosinophil and basophil myelocytes are present, and occasional myeloblasts are encountered. The anæmia is of the orthochromic type, and as it becomes more severe, anisocytosis and polychromasia develop, and nucleated red cells appear in the blood. The platelets are normal or slightly increased at the beginning of the disease, but decrease in the terminal phase.

Diagnosis.—This is usually made with ease from the characteristic blood picture and the great splenic enlargement, though difficulty may arise when the white cells fall to normal or subnormal values as a result of excessive treatment or of a natural remission of the disease. In these circumstances the presence of immature white cells and of basophilia may indicate the correct diagnosis. Myeloid leukæmia usually runs true to type and rarely presents an aleukæmic phase. The differential diagnosis of chronic myeloid leukæmia and myelosclerosis may be very difficult but will rarely be of great clinical importance.

Course and Prognosis.—Chronic myeloid leukæmia is invariably fatal. The average duration of life is just over 3 years from the onset of the disease, or 2 years after coming under treatment. There is no evidence that treatment prolongs life, though it greatly increases the comfort of the patient. In any large series exceptional cases are observed in which life is prolonged for 10 to 20 years. One of my cases was under observation for 22 years from age 38 to her death from bilateral hydronephrosis at the age of 60; in her the disease seemed to be of a benign character, and though there was great splenic enlargement, the highest white count was only 35,000, with 26 per cent. myelocytes. At the other extreme are subacute cases which shade indefinitely into acute leukæmia. The prognosis in an individual case will depend on the general condition of the patient and the presence or absence of cachexia, the degree of anæmia, and the height of the white count, very high and also very low values being unfavourable. Enlargement of lymph nodes and the appearance in the blood of large numbers of myeloblasts are each unfavourable signs. (See also under Treatment.)

Treatment.—The treatment of chronic myeloid leukæmia is practically confined to the use of X-rays and arsenic. Both agents owe their reputation to their remarkable power of producing a temporary remission in the disease.

The natural course of chronic myeloid leukæmia is steadily downhill, and during the latter half of the untreated disease the patient is confined to his bed, cachectic and miserable. After a course of treatment with X-rays or arsenic, the patient is restored to what he feels his normal condition. The spleen usually remains enlarged and the blood abnormal, but in rare cases the blood returns almost to normal and the spleen recedes beneath the costal margin. Such a remission lasts from a few months to a year, when repetition of the treatment again produces improvement, though not so complete as before. After a varied number of cycles treatment finally becomes ineffective, and a time arrives when despite all efforts the patient becomes steadily worse. The period of decline is usually swift, and in the majority of cases death occurs within four or five months of entering this final phase. Iron and to a less extent liver are valuable adjuvants to X-ray therapy. Splenectomy is contra-indicated in leukæmia, and leucotoxic drugs such as benzol and thorium-X are not without danger. Anti-leucocytic sera have been employed, but have not emerged from an experimental stage.

2. Chronic Lymphatic Leukæmia.

Synonym.—Chronic Lymphadenosis.

Definition.—A chronic overgrowth of the lymphatic tissue throughout the body, accompanied by an increased number of lymphocytes in the blood.

Ætiology.—The disease is one of middle and later life, and is never met in children. The average age of incidence is 55, over ten years later than chronic myeloid leukæmia. Males are affected about four times as often as females. The cause is not known. Chronic lymphatic leukæmia is much the rarest of the three main types of leukæmia, and it accounts for less than one-sixth of all the cases.

Pathology.—Post mortem, the striking feature is the enlargement of the lymph-glands and other lymphoid tissues. The glands are seldom larger than a walnut, discrete, homogeneous, and pinkish-grey on section. The lymphoid tissue of the pharynx is hypertrophied, and lymphoid nodules may be present in the intestines, the kidneys and elsewhere. The liver and spleen are uniformly enlarged, the bone-marrow is hyperplastic, and grey or greyish-red in colour.

Symptoms.—The disease may be present for months or years before the patient feels it necessary to consult a physician. Swelling of the glands is usually the first symptom to attract attention, or the patient may complain of increasing tiredness and loss of weight. Less frequently enlargement of the tonsils is first noticed, or enlarged glands and spleen are discovered by chance during a routine examination. In exceptional cases a tumour extirpated by the surgeon is found to be a lymphoma, and subsequent examination of the blood reveals chronic lymphatic leukæmia. Other early symptoms are itching eruptions of the skin, and impotence.

In typical cases all the superficial lymph-glands are enlarged. The enlargement is moderate and the glands are rarely so big as in Hodgkin's disease or lympho-sarcoma. They are freely movable and not adherent to one another, moderately hard, and do not alter in consistence during the course of the disease. Spontaneous fluctuations in their size may occur. In atypical cases only one group of glands may be enlarged. The tonsils may

be hypertrophied, the spleen is nearly always palpable, though it does not often extend more than a hand's breadth below the costal margin, and the liver is enlarged. Tenderness of the sternum or of the long bones is unusual. Hyperplasia of the lymphoid tissue in various parts of the body may lead to the formation of tumours or other unusual symptoms. Nodular lesions, infiltrations and actual tumours may develop in the skin. Enlargement of the thymus and the mediastinal lymph-glands may produce the signs of an intrathoracic tumour. Lymphomata may develop in the breast or other organs. The salivary and lachrymal glands may be symmetrically enlarged, producing one of the varieties of Mikulicz's syndrome.

The Blood.—The red cells and hæmoglobin are unaffected in the early stages, but, later, severe anæmia develops, with anisocytosis, polychromasia and nucleated red cells. The platelets are unaffected till the end, and hæmorrhage is rare. The total white count is increased, usually to about 200,000 cells per c.mm., but not to the high level seen in chronic myeloid leukæmia. Lymphocytes predominate and may constitute 95 to 99 per cent. of the white cells. The majority are small lymphocytes, though a few large lymphocytes are nearly always present. The nuclei may be more deeply indented than normal, and azur-granules are usually absent. The absolute number of polymorphs is unaltered, and no myelocytes are present. It is probable that the proliferation of lymphoid tissue in the glands and elsewhere may precede by some time the increase of lymphocytes in the blood stream. In rare cases the blood is normal when the patient first comes under observation, but, later, the characteristic picture develops (*aleukæmic leukæmia*); or the total white count may not be increased, though there is a high percentage of lymphocytes (*leucopenic leukæmia*).

Diagnosis.—Only in the rare aleukæmic cases is diagnosis difficult. Points of importance are the generalised enlargement of the lymph-glands, their uniform consistence and moderate size, and the enlargement of the liver and spleen. Biopsy of a gland or sternal puncture may assist.

Prognosis.—The disease is invariably fatal. The average duration is 3½ years from the onset, or about 18 months after coming under treatment. A few cases are more chronic, and exceptionally life may be prolonged for 10, 15 or 20 years. Death occurs from cachexia, hæmorrhage, or most commonly from intercurrent infection, sepsis being a very dangerous complication. It is doubtful whether treatment greatly modifies the course of the disease.

Treatment.—X-rays should be applied to the lymph-glands, but not to the spleen, as irradiation of the spleen produces little benefit and is often followed by severe reactions. Arsenic and ultra-violet radiation may also be employed.

3. Acute Leukæmia.

Ætiology.—Acute leukæmia is not a very rare disease, but many cases go unrecognised, because of the close simulation of other diseases and the difficulty of diagnosis without careful examination of the blood. It is more frequent in childhood and early adult life, but may affect any age. Males predominate in a ratio of about 2 to 1.

Symptoms.—The onset is usually abrupt, and more than half the cases begin with symptoms regarded as a cold, influenza or bronchitis; it is only

when the infection fails to respond to treatment and the patient remains prostrated that a more serious disease is suspected. Other early symptoms are ulcerative stomatitis, or tonsillar enlargement with sore throat, and some cases first come under the physician's care after a prolonged hæmorrhage from tonsillectomy, dental extraction or some trifling operation, which has left the patient exsanguinated. The course of the disease varies from fulminating cases in which the patient succumbs within a week, through cases of average acuteness with a duration of less than 2 months, to subacute cases which shade indefinitely into chronic leukæmia. Usually the rapid development of anæmia, weakness and loss of weight soon compels the patient to take to his bed. He complains of sore throat, headache and pain in the bones. The temperature becomes high and purpuric manifestations set in, which aggravate the anæmia or bring the patient's sufferings to an abrupt termination by loss of blood or cerebral hæmorrhage.

On examination the extreme pallor and the enlargement of the superficial lymph-glands, especially those in the neck, first attract attention. The pallor is most striking when there are in addition purpuric hæmorrhages into the skin, varying in extent from a pinpoint to large patches which may break down and ulcerate. The size of the spleen varies; usually it is easily palpable, but it may not be felt, or it may be greatly enlarged. The liver may be enlarged. The lungs may show bronchitis, broncho-pneumonia, or pleurisy, with or without effusion. Pericarditis and endocarditis may occur. The mind usually remains clear to the end. Certain symptoms may be so prominent as to colour the whole clinical picture and give a special aspect to the disease. In the anginal type, there is necrotic ulceration of the tonsils or other areas of the buccopharyngeal mucous membrane, or bleeding from the gums, complicated by secondary infection. In the hæmorrhagic type, purpura and hæmorrhages are the predominant features, and the disease may be mistaken for purpura hæmorrhagica. There may be hæmorrhage from any of the mucosæ, and in one of my cases there was so much blood in the urine that firm clots formed in both pelves and ureters, leading to death from suppression of urine. Disturbances of vision or deafness may result from hæmorrhage into the retina or the labyrinth. The fever and slight splenomegaly may be suggestive of some systemic infection, and there may be leucopenia and an eruption resembling the rose spots of typhoid fever. Bone pains may suggest the diagnosis of acute rheumatism, and there may even be serous effusion into the joints.

In the more subacute forms of the disease, tumours may develop in various parts of the body. They are composed of undifferentiated white cells and infiltrate the surrounding tissues like a malignant growth. Plum-coloured nodules appear in the skin or in the gastro-intestinal tract, in the latter situation leading to vomiting or profuse diarrhœa, often blood-stained in character, or to intussusception of the bowel. In the abdomen or in the mediastinum large growths may develop from the lymph nodes or the thymus, compressing and infiltrating the adjacent structures. Tumours of the bones have been distinguished by the special title of *chloroma*, owing to the greenish colour sometimes seen in the freshly cut surface of the growth. They have a predilection for the subperiosteum of the orbit, and cause headache, deformity of the temporal and frontal bones, exophthalmos, proptosis, papilloedema and swelling of the veins of the head, neck and

face. They may, however, occur in other parts of the skeleton, and sometimes seem to arise within the bone, which is expanded over them in a brittle shell. The spinal meninges may be invaded, with consequent transverse myelitis, while infiltration of the nerve roots leads to peripheral nerve palsies. It is a curious feature of these neoplastic phenomena that they often begin with a very atypical blood picture, the total white count not being greatly increased and in rare cases the differential count being normal at the onset, though the typical blood picture of leukæmia appears later.

Hæmatology and Pathology.—The outstanding feature of the blood in acute leukæmia is the presence of a large number of mononuclear cells of a primitive type, except in rare cases of acute lymphatic leukæmia in which the predominant cells may be typical lymphocytes. In something like 90 per cent. of all cases of acute leukæmia these primitive cells belong to the myeloid series, the majority being myeloblasts. They are usually larger than the normal white cells; their nucleus, which is round or oval, consists of a pale-staining chromatin reticulum in which 4 or 5 nucleoli may be distinguished; the deep blue cytoplasm contains no granules. Careful staining often reveals some cells with a few myelocyte granules, and a larger or smaller number of typical myelocytes may be present, especially in the more chronic cases. The total white count is rarely high in the early stages of the disease, usually not exceeding 25,000 to 30,000 per c.mm., but as a rule there is a rapid rise to 100,000 or more before the termination. Primitive cells constitute 90 per cent. or more of the white blood cells. Sometimes the total number of white cells is diminished and the count may be below 1000, the majority of the cells being myeloblasts. Such *leucopenic* cases are very prone to necrotic ulcerations and infectious complications. Much more rarely both the total and the differential white count are normal at the onset of the disease, as if the morbid process had not yet invaded the blood stream—*aleukæmic leukæmia*. The overgrowth of the primitive white cells in the marrow and the hæmorrhages soon lead to a profound anæmia, usually of an aplastic or hypochromic type. In very exceptional cases numerous normoblasts and megaloblasts appear in the blood stream, there may be frank megalocytosis, van den Bergh's reaction is positive, and at post-mortem excess of iron pigment may be found in the liver and spleen. The number of platelets is diminished in almost all cases, and sooner or later this is reflected in the hæmorrhagic character of the disease. The bleeding-time is prolonged, the tourniquet test is positive, and the clot may not retract well.

The post-mortem findings vary only slightly from those of chronic leukæmia. There is diffuse hyperplasia of the leucopoietic tissues in the marrow, lymph-glands and spleen, and all the tissues are infiltrated with myeloblasts, which may form nodules or tumour-like masses in various situations. Terminal hæmorrhagic and infectious lesions are rarely absent.

Diagnosis.—Acute leukæmia may simulate a number of diseases, among which may be mentioned the severe systemic infections, septic or diphtheritic inflammation of the mouth and throat, scurvy and the hæmorrhagic diseases, malignant disease or tumours of bone. Usually the blood picture will be decisive, but the possibility of agranulocytosis or of septic infection should be remembered in cases in which only a few immature white cells are present

in the blood. Glandular fever may cause confusion in the early stages, but the benign course and the absence of anæmia and hæmorrhages will soon differentiate it from leukæmia; in doubtful cases the heterophil antibody reaction, a serological test which is positive in glandular fever and negative in leukæmia, may be employed. The blood picture in acute leukæmia is sometimes suggestive of pernicious anæmia, but the other symptoms of that disease and its favourable response to liver are absent. In difficult cases examination of a bone-marrow smear obtained by sternal puncture may be decisive.

Prognosis and Treatment.—Few diseases are more tragic than acute leukæmia, as it is invariably fatal and it so often affects lives which seemed full of promise. Onset at an early age, high fever and great immaturity of white cells, all point to a speedy fatal issue. Death often comes by intercurrent infection, especially in the leucopenic cases, or as a result of hæmorrhage. Rarely the disease may pass into a subacute or chronic form, and death be postponed for a year or longer. Treatment is mainly directed to checking infection, especially about the mouth and throat, and preventing hæmorrhage. Intravenous injections of neoarsphenamine may cause the necrotic ulcerations to heal, and they may also be swabbed with a paint of equal parts of Fowler's solution, tincture of ipecacuanha and glycerin. Blood transfusion may bring the patient into a suitable condition for X-ray treatment, which is otherwise contra-indicated by the low number of normal polymorphonuclear cells, but any improvement is usually evanescent and it rarely does more than protract a painful situation.

THE HÆMORRHAGIC DISEASES

The hæmorrhagic diseases may be arbitrarily classified into those which are due to defective coagulation of the blood and those in which the blood clots normally. According to the theory of blood coagulation most widely held at the present time, a ferment precursor prothrombin is converted into thrombin in the presence of calcium and tissue derivatives (thrombokinase or thromboplastin). The thrombin then reacts with the fibrinogen of the plasma to produce fibrin. It is doubtful whether the clotting process is ever affected by shortage of calcium. Deficiency of fibrinogen has been observed as an excessively rare congenital abnormality—*fibrinopenia*. The only two important conditions in which coagulation is impaired are hypoprothrombinæmia and hæmophilia. Prothrombin is formed in the liver under the influence of the fat-soluble vitamin K. Prothrombin deficiency may therefore occur under the following conditions:

(i) In the newly-born (*melæna neonatorum*). The factors here are the small amount of prothrombin in the blood at birth, deficient intake of vitamin K in the first few days of life and absence of saprophytic bacterial activity in the intestine—bacteria synthesise vitamin K.

(ii) Deficient intake of vitamin K in states of extreme malnutrition.

(iii) Deficient absorption of vitamin K in intestinal diseases and fatty diarrhœa, as in obstructive jaundice, cœliac disease and sprue.

(iv) Deficient utilisation of vitamin K when the liver parenchyma is diseased.

Hypoprothrombinæmia is recognised by the fact that the blood does not coagulate normally even in the presence of an excess of thrombokinase. It can be prevented or treated by the administration of vitamin K. This can be given by mouth, together with bile salts to ensure its absorption, but at the time of writing the best method appears to be the injection of the synthetic vitamin derivative, methyl-naphthoquinone, 5 to 10 mg. dissolved in oil by intramuscular injection daily. In hæmophilia the blood coagulates normally on the addition of thrombokinase, and the disease is therefore probably due to inadequate release of thrombokinase.

1. PURPURA

In the narrow sense purpura refers merely to the occurrence of bleeding in the skin in the form of petechiæ, macules or larger areas. In the wider sense it connotes a group of diseases which are characterised not only by these cutaneous lesions but also by bleeding from the mucosæ and internally. Purpura is often classified into thrombocytopenic and non-thrombocytopenic forms, but there is so much overlap between these two that the distinction often falls to the ground. Hæmostasis appears normally to occur in two stages, first, contraction of the damaged vessel, and second, occlusion by thrombosis. In all the purpuras, whether thrombocytopenic or non-thrombocytopenic, the first stage of hæmostasis appears to be at fault, the capillaries do not retract properly when they are injured and the bleeding time is prolonged. In hæmophilia the second stage is at fault and though hæmostasis begins normally, bleeding recurs after a short interval.

The blood platelets.—The platelets are the third formed element in the circulating blood. They are spherical or oval, non-nucleated disks, with an average diameter of 2 to 3 microns, and with a hyaline cytoplasm which contains numerous granules. The average number of platelets is from 250,000 to 450,000 per c.mm., but there are great variations in health and according to the method of estimation employed. The platelets are believed to be produced by the megakaryocytes in the bone-marrow, and after a brief life of a few days they are phagocyted by the cells of the reticulo-endothelial system. Large numbers of platelets are present in the spleen, but it is not certain whether they are held there in reserve or in process of destruction. The platelets play an important part in the arrest of hæmorrhage, sealing wounds in the endothelial lining of the vessels, promoting the coagulation of the blood and securing the firm adhesion of the clot. Purpuric symptoms commonly appear when the blood platelets fall below 40,000 per c.mm. The following signs may also be observed in thromobocytopenic purpura: 1. The platelets are very variable in size and shape, and giant platelets may be present. 2. The blood clots in the normal time, but the clot does not retract and express the serum as rapidly and completely as in health. 3. The bleeding time is greatly increased. If the blood from a sharp prick in the finger is soaked off with a filter paper without pressure every 30 seconds, bleeding normally ceases in one to two and a half minutes, but if the platelets are defective it may be prolonged even to an hour or more. 4. The capillaries are more fragile than normal. The sphygmomanometer is applied to the upper arm and the pressure is maintained midway between the systolic and

diastolic level for five minutes. When the platelets are defective, a coarse purpuric rash may appear on the lower arm.

The endothelium.—A hæmorrhagic tendency due to a pure endothelial lesion is characteristic of scurvy, in which the plasma and the platelets are normal but the fragility of the capillaries is much increased. The same is true of the purpura of old age and nervous purpuras, such as stigmatisation. The hæmorrhagic states present in uræmia and other cachectic conditions are probably due to endothelial damage. When hæmorrhagic states are due to lesions of the capillaries, plasma may also pass through the endothelial lining, producing wheals, local œdema of the tissues and urticaria, and the purpuric areas may be elevated above the surrounding skin.

2. SYMPTOMATIC HÆMORRHAGIC STATES

Acquired hæmorrhagic states due to defective coagulation of the blood have already been discussed and it has been pointed out that the most important of them are due to defiency of prothrombin. Hæmorrhagic tendencies in which the blood coagulation is normal may develop in a heterogeneous collection of diseases, and it is difficult to present the subject at all formally.

1. The most important group is constituted by the *infectious diseases.* Purpura and a hæmorrhagic tendency have been observed in infections with the pyogenic cocci, scarlatina, chicken-pox, diphtheria, the enteric fevers, typhus, malaria, and gonococcal and meningococcal septicæmia. They have also been observed in chronic septic infections, such as focal sepsis and malignant endocarditis, and in tuberculosis, especially the miliary form. In all such conditions we have reason to believe that the endothelial lining of the vessels is damaged. The platelet count varies from case to case. It may be increased, and then thrombosis may develop in the midst of hæmorrhagic manifestations; it may be normal; or it may be diminished, when the hæmorrhagic tendency may be very severe, such cases being known as purpura fulminans. In typical cases the platelets are diminished during the acute period of the illness, but increase in convalescence and afterwards fall to normal limits. The cause of the thrombocytopenia of infections is not known. It has been suggested that there is an increased utilisation of platelets in such illnesses, either to combat the infection or to repair the lesions of the vessel walls. In some cases it is undoubtedly due to depression of the function of the bone-marrow in producing platelets, and this should be suspected more especially when there is leucopenia also. We shall see later that the spleen plays an important part in one group of hæmorrhagic states associated with thrombocytopenia, but I do not think there is any evidence to inculpate the spleen in the hæmorrhagic states which complicate infectious illnesses, and the splenectomy should not be performed. Treatment should be directed to the primary malady, and the hæmorrhages should be controlled by local measures, supported if necessary by transfusions.

2. A second group of symptomatic hæmorrhagic states is constituted by *chronic nutritional disturbances and cachexias,* of which chronic nephritis is an example. Here also we may mention the purpura which occasionally occurs in pregnancy. Malignant disease of the stomach is occasionally complicated by purpura hæmorrhagica; in the cases I have seen there was extreme thrombocytopenia.

3. A third group is produced by *organic and inorganic poisons*, such as salvarsan and sanocrysin. Here there may be both endothelial damage and thrombocytopenia.

4. A fourth group is associated with *chronic splenomegaly*, such as occurs in splenic anæmia and Gaucher's disease. Here there is thrombocytopenia, which is usually relieved by splenectomy.

5. A fifth group is the result of *diseases of the blood-forming organs*. The proliferation in the bone-marrow of the megaloblasts in pernicious anæmia, or of the immature white cells in leukæmia, may cause a pressure atrophy of the megakaryocytes and consequent thrombocytopenia. The same effect may be due to other tumour-like lesions of the bone-marrow.

Aplastic anæmia requires special mention. In discussing this disease I have already described cases in which the red cells are predominantly affected (aplastic anæmia), and others in which the white cells are predominantly affected (agranulocytosis). Cases also occur in which the platelets are chiefly affected, and they are known as *malignant thrombocytopenia*, or aleukia hæmorrhagica. The term "aleukia hæmorrhagica" is unnecessary, but it stresses the leucopenia, which is nearly always present in these cases. The disease should be recognised by its acute and rapidly fatal course and by the absence of any signs of regeneration in the white cells or the red cells. The spleen is not enlarged, and splenectomy is useless. Treatment should be directed to keeping the patient alive by transfusions in the hope that the bone-marrow may recover its functions.

Treatment.—General and local measures of value in all forms of hæmorrhagic tendency may conveniently be discussed here. The only reliable general remedy is the administration of normal human blood, as an ordinary transfusion in severe cases and as intramuscular injections of 10 to 20 c.c. daily in mild cases. Cotarnine hydrochloride, three to four intramuscular injections of 1 c.c. of a 10 per cent. solution daily, is believed to be of value in uterine bleeding, while Congo Red 10 c.c. of 1 per cent. solution intravenously, may be used in any hæmorrhage, though it is most commonly employed for hæmatemesis, melæna and hæmoptysis. Liver and vitamin C, more especially by injection, have been recommended for all kinds of hæmorrhage; I have never been persuaded that they have any effect other than their specific action in pernicious anæmia and scurvy respectively. In more chronic cases ultraviolet radiation and high vitamin diets are used, but again with little real assurance. Recently the injection of Moccasin snake venom was recommended for chronic and recurrent bleeding, especially of a purpuric type, but it is now generally held to be worthless. On the other hand, local treatment of hæmorrhage, especially in hæmophilia and purpura, has been revolutionised by the local application of snake venom, which is a powerful coagulant. The venom of Russell's viper (1 in 10,000 solution) or of the Australian tiger snake (1 in 5000 solution) has been chiefly used. Loose clot is washed away from the bleeding point with hot water, and tampons or other appropriate dressings soaked in the venom solution are then applied. With the use of snake venom it is now possible to repair wounds which would previously have been fatal. Heat is a valuable agent for checking hæmorrhage and may be applied as hot water (42° C.) or better, especially in hæmorrhage from an inaccessible cavity, as a stream of hot air.

3. MELÆNA NEONATORUM

Synonym.—Hæmorrhagic Disease of the Newly-born.

Ætiology and Pathology.—The blood is cytologically normal and the condition is essentially due to hypoprothrombinæmia. Both the bleeding time and the clotting time may be greatly prolonged. The incidence has been placed as high as 1 per cent. of all births, male and female. Heredity seems to play no part. In some cases acute gastric and duodenal ulcers have been found at autopsy, but it is more probable that these represent necrosed areas from submucous hæmorrhages than that they are the cause of the bleeding.

Symptoms.—The bleeding is spontaneous, commencing at any time in the first week or two of life, most commonly on the third or fourth day. The bowel is the usual site of hæmorrhage, but blood may also ooze from the mouth, nose and urinary tract, or be extravasated into the viscera or the cavities of the body. If the disease is not immediately treated, death from hæmorrhage and shock soon occurs.

Diagnosis.—This can be confirmed if necessary by estimating the prothrombin time. Hæmorrhagic states may occur in the new-born as a result of sepsis, syphilis, thrombocytopenia and other blood dyscrasias, but all are rare.

Prognosis and Treatment.—The prognosis depends on the promptitude of the treatment and the amount of blood already lost. It has been suggested that vitamin K, given prophylactically to the mother, will diminish the incidence of both intracranial bleeding and hæmorrhagic disease in the newly-born. By the time the condition develops, it is too late to use vitamin K, which has a latent period of 12 to 24 hours before acting. For treatment, 10 to 15 c.c. of fresh human blood should be injected subcutaneously once or twice daily, when the bleeding usually stops quickly and the infant makes a good recovery. No typing of the blood is necessary ; a little citrate may be added to prevent coagulation. During treatment the infant is kept as quiet as possible and not lifted from the cot. He can be fed by a bottle or spoon with breast milk, or if necessary, with an artificial food.

4. ESSENTIAL THROMBOCYTOPENIA

Synonyms.—Idiopathic Purpura Hæmorrhagica ; Hæmogenia ; Morbus Maculosus Hæmorrhagicus of Werlhof.

Definition.—A disease characterised by multiple hæmorrhages in the skin or from the mucous membranes, a reduced platelet count, a prolonged bleeding time, but a normal coagulation time.

Ætiology and Pathology.—Some 30 per cent. of the cases occur in the first decade of life, and the disease is infrequent after the age of 40. A few cases have been traced to idiosyncrasy for certain foods, such as milk, and for certain drugs, such as quinine or sedormid. Ingestion of the offending food or drug is followed within a few hours by the onset of thrombocytopenia and purpura. Another group of cases, occurring from one to three weeks after an infection such as tonsillitis, is suggestive of sensitisation to the infecting organism or its products. A small group is associated with malignant

disease, particularly metastases in the bone-marrow. The majority remain unexplained. The bone-marrow contains rather more than its normal complement of megakaryoblasts and megakaryocytes, and this is suggestive of an arrest of maturation of the platelets comparable with the arrest of maturation of the megaloblasts in Addison's anæmia and of the leucocytes in agranulocytosis. The spleen shows no pathognomonic changes.

Symptoms.—An acute and a chronic form are described. The acute form is uncommon. It begins suddenly and without warning, though sometimes there is a history of an acute infection a couple of weeks before. There is no pyrexia and the spleen is not palpable. Purpuric patches appear in the skin, of variable size and of irregular distribution. There is no erythema or whealing. Hæmorrhages occur from any of the mucosæ, the nose and mouth, the alimentary canal and the urogenital tract. The slightest injury gives rise to excessive bleeding, or the formation of large hæmatomata. The bleeding time is greatly prolonged, and the tourniquet test is positive. Examination of the blood reveals a thrombocytopenia, platelets being perhaps completely absent; there is usually a slight leucocytosis, and immature red cells and even normoblasts may be poured out to combat the anæmia. Recovery occurs in a few days or at most a few weeks, and the platelet count returns to normal. This may be the only attack, but in other patients a recurrence months or years later reveals that the disease is present in a relapsing form.

The chronic form of the disease, which accounts for 75 per cent. of the cases, may be of a continuous or of a relapsing type. In many cases the disease first manifests itself in childhood. In the continuous type there is persistent thrombocytopenia, with exacerbations of symptoms due to fluctuations of the platelets above and below the critical level of about 40,000 per c.mm., or to the effects of trauma or intercurrent infection. In the relapsing type there are long intervals of freedom during which the platelet count is quite normal. There may be persistent purpura, especially on the legs, or the parts exposed to trauma, or purpura may be completely absent. The spleen may be enlarged. There is a tendency for hæmorrhages to recur from the same site, as if it were an area of predilection, so that one patient may suffer from hæmatemeses, another from hæmaturia, another from menorrhagia. In my experience the disease becomes less troublesome in later life, even though the platelets remain at the same low level.

Diagnosis.—The diagnosis depends on the thrombocytopenia and the associated symptoms of platelet shortage, but it should be remembered that the platelets may be normal in the free intervals. For differential diagnosis the section on symptomatic hæmorrhagic states should be consulted; the absence of toxæmia and of joint pains is an important difference from these conditions and also from Henoch's purpura. Acute leukæmia is an important cause of purpura hæmorrhagica, which should be excluded by the differential white blood count. Most difficulty will be experienced in distinguishing the acute form of essential thrombocytopenia from the malignant purpura of aplasia of the bone-marrow. In malignant thrombocytopenia there is usually leucopenia and no sign of regeneration of red cells. In the chronic form of essential thrombocytopenia it is rather easy to overlook the possibility of a hæmorrhagic disease altogether, especially when there is no purpura and the bleeding is always from one organ. On this account this diagnosis should

always be considered in cases of symptomless hæmaturia, or hæmatemesis, or the like, or ill-advised operations may be performed.

Prognosis.—Death may occur in the acute attacks, or irretrievable damage be done, as by hæmorrhage into the vitreous humour of the eye or into the central nervous system. Nevertheless the disease is relatively benign, and the physician should not allow his judgment to be impaired by the alarm that is always felt in the presence of a hæmorrhagic disorder. One of my patients had multiple cerebral hæmorrhages, in addition to external bleeding which made him profoundly anæmic. He was treated with transfusions and symptomatic remedies, as he firmly refused splenectomy, and he remained thrombocytopenic, anæmic and ill for several months. A year later he was perfectly well, working as a railway guard with a normal blood count. This is by no means an isolated example, and the natural tendency of the acute attacks is to recovery.

Treatment.—The remarkable alleviation of the symptoms by splenectomy is very mysterious. The operation was introduced on the theory that the spleen was destroying an excessive number of platelets, but there are many facts which cannot be adapted to this theory. The bleeding may cease immediately the pedicle of the spleen has been tied, and before the platelets have had time to increase. The operation is usually followed by a great rise in the platelet count, but later the platelets may fall to subnormal levels without the recurrence of hæmorrhage. Operation should rarely be performed in acute cases, as the majority recover quickly on medical treatment and those that do not are usually of a type that is not likely to benefit from splenectomy. It is a good working rule to rely on transfusion and general treatment for at least a fortnight before having recourse to splenectomy. In the chronic cases the mortality of splenectomy has fallen to 7 per cent.; of those who survive the operation the immediate results are 85 per cent. cured, 10 per cent. improved and 5 per cent. not improved. Experience has nevertheless shown that splenectomy does not eradicate the cause of the disease, for after an interval of months or years the symptoms recur in about half the patients, though as a rule they are much less troublesome than before the operation. Operation should therefore be restricted to patients in whom the disease is really disabling or is subject to acute exacerbations. Operation should not be performed in patients with a family history of purpura hæmorrhagica. General treatment is on the lines already described (p. 812). Septic foci should be removed and efforts made to exclude sensitisation to foods or drugs. The results of X-ray treatment are at present discordant, but there is some evidence that remissions may be induced by irradiation of the spleen or the bones, and this treatment is worthy of further trial.

5. HENOCH'S PURPURA

Synonyms.—Anaphylactoid Purpura; Hæmorrhagic Capillary Toxicosis; Toxic Purpura.

Definition.—Although the term Henoch's purpura is sometimes restricted to cases characterised by purpura, colic and gastro-intestinal lesions, it is profitable to extend it to a group of non-thrombocytopenic purpuras, which are of obscure origin, and which may be accompanied by urticaria, œdema, swollen joints and various visceral manifestations. For

this reason the milder cases which are known as purpura simplex, and also the peliosis rheumatica or arthritic purpura of Schoenlein are considered under this same heading, for all appear to be manifestations of the same pathological state.

Ætiology and Pathology.—The disease is related to allergic conditions, such as erythema multiforme, erythema nodosum, angioneurotic œdema and serum sickness. The lesions probably result from an abnormal permeability of the capillaries, which allow plasma and blood to escape through their walls. The sensitising agent is not always the same. In some instances it is the streptococcus, the attack following a sore throat, or persisting until a septic focus is drained. In other instances sensitisation to foods has been demonstrated, and the disease has been cured by removing them from the diet.

Symptoms.—The attack is usually preceded by symptoms of general bodily disturbance, such as headache, malaise, loss of appetite, and a rise of temperature. In the mildest cases (purpura simplex) a fine purpuric eruption appears, often affecting the limbs rather symmetrically, and with a special tendency to develop round the hair follicles. In severe cases there may be extensive, irregularly distributed ecchymoses, and there is much œdema of the face. Wheals and pemphigoid lesions may develop, and careful examination will often show that the purpura is not a pure hæmorrhage, but that it is raised or surrounded by a zone of erythema. Successive crops of purpura appear. Bleeding is not necessarily confined to the skin, but may be subperiosteal, intramuscular or intravisceral. Joint pains are rarely absent, though the joints are seldom much swollen, and there may also be myalgia or neuralgia. The gastro-intestinal symptoms take the form of colic, bilious vomiting, and diarrhœa, with blood-mixed stools. The abdominal wall may be rigid, and it may be difficult to differentiate the lesion from an intussusception, which may indeed occur from invagination of a piece of intestine whose walls have been stiffened by the exudation of serum and blood. Similar lesions occur in the urinary tract, but extensive hæmorrhage from the mucosæ is rare. The spleen may be palpable and the urine may contain albumin, blood cells and casts. In rare instances death has occurred from cerebral convulsions, suggestive of acute uræmia; nephritis is, indeed, the most important complication.

The blood is normal, save for a slight anæmia or a mild leucocytosis. The platelets are normal or only slightly diminished, and the coagulation and bleeding times are normal. The tourniquet test may be positive, but in general there is little tendency to spontaneous or excessive external bleeding, and the mucosal hæmorrhages are small and attributable to oozing from areas of œdema and congestion.

Diagnosis.—The disease is not sharply divided from the symptomatic purpuras. It should, however, be clearly differentiated from essential thrombocytopenia and similar blood disorders by the absence of specific changes in the blood, and the presence of signs of toxæmia and increased capillary permeability. Cases with intestinal lesions may closely simulate intussusception, and they may occasionally be complicated by intussusception or peritoneal effusion.

Prognosis.—The disease tends to spontaneous recovery after an illness of a few weeks. Chronic and relapsing cases occur which are very

troublesome, though rarely dangerous. The prognosis is good, except for complications, such as nephritis and intestinal obstruction.

Treatment.—Treatment should be symptomatic and conservative. Incautious attempts at desensitisation may aggravate the disease. Splenectomy is not indicated. In view of the risk of renal damage the patient should be at rest, the diet should be lacto-vegetarian, and the urine should be kept alkaline. No further treatment is necessary in the majority of cases. Chronic cases should be investigated for persistent infection, foci of sepsis, or evidence of protein sensitisation. Large doses of calcium are frequently prescribed, but it is doubtful if they have any value. Non-specific desensitisation may be attempted by subcutaneous injections of horse-serum, 10 to 20 c.c. daily till improvement begins, or by minute doses of tuberculin.

6. HEREDITARY HÆMORRHAGIC STATES

As case histories are more carefully analysed, we are discovering that there are many instances of hereditary hæmorrhagic tendency which differ in pathology from hæmophilia, a disease which has obtained an exaggerated importance because of its prevalence in the royal households of Europe. Further experience may show that the symptoms and the mode of inheritance differ considerably in different family groups of bleeders. A practioner faced with a case which does not square with the classical description of hæmophilia will do well to prepare a careful pedigree and submit the data to an expert hæmatologist or eugenist, for these diseases can rarely be cured and patients are often anxious for advice whereby their transmission can be prevented. In the present state of knowledge we can distinguish the following hereditary tendencies to bleed :

(*a*) Classical hæmophilia (p. 818).

(*b*) Hæmophilia not uncommonly occurs sporadically, in the absence of a family history. Some of these cases are examples of hæmophilia arising *de novo* as a spontaneous mutation ; others are compatible with the transmission of the gene from a remote ancestor, for by the laws of chance there are bound to be some families where the males have escaped inheritance of the defect for several generations and yet it remains latent in the females.

(*c*) Hæmophilia may be atypical in affecting males as well as females, or in combining the features of hæmophilia and hereditary hæmorrhagic purpura. Both these variants of hæmophilia are so uncommon that an error of diagnosis should be suspected.

(*d*) Hereditary fibrinopenia is exceptionally rare.

(*e*) Hereditary hæmorrhagic states in which the coagulation of the blood is normal but the bleeding time is prolonged are by no means infrequent. These states are variously known as hereditary purpura hæmorrhagica ; constitutional hæmogenia ; thrombasthenia of Glanzmann ; thrombopathia of Willebrand-Jürgens ; and hereditary pseudo-hæmophilia. They bear a closer affinity to purpura hæmorrhagica than hæmophilia, and in some families the platelets are reduced. Nevertheless, the patients may suffer from hæmarthrosis. The condition may be transmitted direct from one generation to another, and it often affects females more severely than males. Sporadic cases occur. Splenectomy has no influence on the disease.

(*f*) Hæmorrhagic states apparently hereditary in origin occasionally

occur in which no abnormality can be detected in the blood or vessels by current methods of investigation. Clinically they bear most resemblance to the hereditary purpuras. It is always wise to take seriously the statement that a patient is a bleeder, even though no confirmation can be obtained from the laboratory.

(*g*) Hereditary hæmorrhagic telangiectasia (p. 819) is probably at least as common as hæmophilia.

(*a*) Hæmophilia

Definition. — A rare hereditary disease of males, characterised by a tendency to uncontrollable hæmorrhage and a great prolongation of the coagulation time.

Ætiology.—The disease is inherited by the law of Nasse, according to which it is transmitted only by females and manifested only by males. In Mendelian terminology it is a sex-linked recessive, and theoretically it might be expected to occur in females in the proportion of 1 to 200 affected males.

Pathology.—In contrast to prothrombin deficiency, the blood in hæmophilia clots normally in the presence of excess of thrombokinase. The disease has therefore been attributed to inadequate release of thrombokinase, and this again to undue stability of the platelets.

Symptoms.—The disease usually manifests itself in early life, but not at birth, so that there is no excessive hæmorrhage from the cord. Severe bleeding at circumcision is common, and in 60 to 70 per cent. of recorded cases the disease was recognised before the second year. It is doubtful whether the bleeding is ever spontaneous, and there is no purpura, but excessive hæmorrhage may occur from a mere scratch, and great bruises or ecchymoses from trivial injuries. Some patients cannot use a tooth-brush on account of bleeding from the gums. Epistaxis is common, but internal bleeding is unusual, though hæmaturia, melæna and hæmatomyelia have been described. Trauma and dental extraction are the most usual causes of severe hæmorrhage, and a rick of the muscles which would pass unnoticed in an ordinary boy may lead to an extensive intramuscular hæmorrhage which leaves the patient exsanguinated. The bleeding is not so much severe as persistent; hence it is rare for the hæmophiliac to die of a sudden profuse hæmorrhage, he rather fades out of life owing to the inability to stop the slow continued loss of blood.

The most remarkable form of hæmorrhage, and one which is common, is into the cavities of the joints. The joints which suffer most often are the knees and elbows, but any joints may be affected. The swelling and effusion take place with great rapidity, and with a great deal of pain. The joint is hot, tender, reddened, and the surrounding tissues swollen. The temperature is raised to 101° or 102° F. The effusion is almost pure blood, but as absorption proceeds it becomes a dirty brown colour, which stains the synovial membrane and the cartilages of the joint. It is sometimes absorbed rapidly, and the joint restored to complete mobility. When absorption is slow or effusions repeated, contraction and ankylosis may cripple the patient permanently. In a joint often affected, there is always considerable destruction of the cartilages and of the ligaments, with the result that the bones are exposed and undergo changes resembling those of osteo-arthritis. Osteophyte formation is, however, rare, and so is bony ankylosis. Fibrous ankylosis is, on the

other hand, common. The spleen is not palpable. Hæmophiliacs are usually weakly individuals.

Diagnosis.—The diagnosis is based on the family history and on the delayed coagulation of the blood; the cytology and chemistry of the blood are normal. The joints are sometimes mistaken for tuberculous joints. A more serious error is to incise a hæmatoma on the mistaken diagnosis of an abscess. Hæmophilia should be differentiated from other hereditary hæmorrhagic states and from acquired conditions, such as essential thrombocytopenia.

Prognosis.—It is said that less than 12 per cent. of hæmophiliacs survive to puberty, but the disease undoubtedly becomes less severe in later life, though still present. A peculiar feature of the disease is its variability, the blood at times clotting almost normally, at other times seeming almost incoagulable, and if the patient survives a severe hæmorrhage there is often a temporary improvement in the blood.

Treatment.—Treatment is unsatisfactory, and it is much better to try to stamp out the disease by discouraging the reproduction of affected families. The only members of a hæmophiliac family who can safely beget children are the unaffected males. Sufferers from the disease should be protected from trauma as far as possible, and operations should be discouraged unless they are essential to life. Transfusion is the best general treatment and snake venom the best local treatment. When a joint is distended with blood it should be aspirated; needle punctures rarely bleed much.

(*b*) Hereditary Hæmorrhagic Telangiectasia

Definition.—A hereditary disease characterised by multiple telangiectases, which cause hæmorrhages from various sources, especially the nose.

Ætiology.—The disease is not strictly a blood disease, but a hereditary dystrophy of the capillary system, which is transmitted directly from generation to generation, affecting both sexes equally and behaving as a Mendelian dominant. It is, in my experience, at least as common as hæmophilia.

Symptoms.—Epistaxis generally begins in childhood and before any cutaneous telangiectases have been recognised, but it tends to become more frequent and severe with advancing years. The telangiectases are not present at birth, and are sometimes not noticed till middle life. They vary in kind, appearing as dilated venules; spider capillary networks; punctate red or purple spots and blebs; and raised nævi up to an inch in diameter. They are most common about the face, nose and mouth, and the trunk and limbs are generally spared, except for the tips of the fingers. Epistaxis is the common complaint, but external bleeding, hæmoptysis, gastrostaxis, hæmaturia, or cerebral hæmorrhage may occur. The blood is normal, except for the anæmia induced by the bleeding.

Diagnosis.—This depends on the family history and the presence of telangiectases, and both these may be missed if they are not sought for. Few telangiectases may be visible, and epistaxis or alimentary hæmorrhage may be the presenting symptom. Many cases are first seen by the rhinologist.

Prognosis and Treatment.—There is no curative treatment, and death from hæmorrhage occurs in a considerable percentage of the cases. Affected members of these families should, therefore, be strongly advised against having children, as half of their offspring will inherit the disease. Treatment of the nævi by cauterisation or radium is only moderately successful.

PROPHYLAXIS AND TREATMENT OF ANÆMIA

Prophylactic.—A number of the diseases of the blood-forming organs, such as acholuric jaundice and hæmophilia, are pure hereditary dystrophies, and rational treatment should be directed not to the individual but to the stock, all those who carry the morbid trait being advised against reproduction. Prophylaxis of the acquired forms of anæmia is not often feasible, but the relation of anæmia to nutritional disturbances should be emphasised and especial care should be taken in the growing periods of life, childhood and pregnancy, that the diet contains a sufficiency of iron and protein.

Treatment.—Good treatment is not possible without exact diagnosis, and if a patient is ill enough to be treated for anæmia, then he or she is ill enough for an examination of the blood to be necessary. It is surprising how often debility is mistaken for anæmia, but the distinction is often difficult on clinical examination. Much time and money are wasted by the prescription of remedies which are not indicated, and the physician is confused and unable to evaluate the effects of treatment. It is a simple matter to test the hæmoglobin, after which a more detailed examination of the blood can be advised if anæmia is found. Many disturbances of the blood are of a highly specific nature, and the appropriate treatment can only be elucidated by careful clinical and hæmatological study. It is no use prescribing iron for the anæmia of scurvy, or vitamin C for the anæmia of myxœdema.

Symptomatic disturbances of the blood-forming organs, which are far commoner than their primary diseases, usually recover spontaneously if the cause can be removed ; if it cannot, they rarely respond well to symptomatic treatment. Many remedies for anæmia have gained an unfounded reputation by being administered to patients who would have recovered equally rapidly without treatment. It is surprising, for example, how swiftly the blood may be regenerated after a severe hæmorrhage. On the other hand, in chronic and persistent anæmias the dosage of the drugs which are useful in treatment is much higher, and the period necessary for treatment is much longer, than is often realised. Treatment can be checked by the reticulocyte crisis, which should occur in the first fortnight, and by the rise in hæmoglobin, which should be over 1 per cent. a day, or approximately 10 per cent. a week in a severe anæmia receiving optimal treatment. Patients who are severely anæmic should be confined to bed, for this makes a great difference to the speed of regeneration of the blood. A generous mixed diet should be given, rich in vitamins, and liver or kidney should be taken two or three times a week. Fresh air and sunshine or ultra-violet therapy also improve the patient's condition, but too much should not be expected from these ancillary treatments, which by themselves will rarely influence a severe anæmia.

Iron is of value in the majority of anæmias of low colour index, especially those which are due to chronic hæmorrhage, or to defective absorption of iron (idiopathic hypochromic anæmia). Recent studies have shown that the various preparations of iron differ greatly in their activity. Elemental iron as in ferrum redactum, is rather inactive, on account of its insolubility. The ferrous salts are the most active, next the scale preparations, and then the ferric salts; organic preparations of iron, such as hæmoglobin, in which the iron is "masked," have no therapeutic activity. Effective doses of substances in common use are: ferrous chloride, or exsiccated ferrous sulphate, in each case 3 grains thrice daily after food; Blaud's pill (ferrous carbonate), which must be fresh and is often best prescribed as a powder, in a dosage of 10 to 15 grains thrice daily after food; and iron and ammonium citrate, in a fluid mixture, 20 to 40 grains thrice daily after food. Intolerance of iron is very unusual, and is usually due to suggestion; the digestion improves in most cases, and with large doses diarrhœa is a more common complaint than constipation. Menorrhagia sometimes occurs, especially in women about the menopause, and may require special treatment. Iron should not be given by injection. The majority of ampoules of iron preparations which are sold contain infinitesimal amounts of the metal, and are ineffective; potent preparations cause much pain, and the injections may lead to iron poisoning—headache, vomiting, paralysis and even death. A patient too ill to take iron by mouth should be transfused.

Liver and stomach are often prescribed as if they were a panacea for all forms of anæmia, but in my experience they are of no value except in the small and well-defined group composed of pernicious anæmia and allied megalocytic anæmias. Whole liver, whether raw or cooked, is not to be recommended, as it is impossible for a patient to take it in adequate dosage or for a sufficient period of time. Whenever possible parenteral therapy should be used as it is the most economical and effective. Superconcentrated extracts such as anahæmin have been introduced recently. They are often better tolerated than the cruder extracts but there is evidence that something may be lost by these processes and such extracts may fail in nutritional macrocytic anæmia and anæmia due to intestinal disease unless given in extravagant amounts. The Anti-Anæmia Preparations Advisory Board of the United States Pharmacopœia in 1938 decreed that it would not assign any preparation of injectable liver extract a strength greater than 15 units per c.c. liquor hepatis purificatus, U.S.P., contains 10 units per c.c. and there are numerous British intramuscular extracts of the same type. In a case of pernicious anæmia of average severity treatment should be begun by the intramuscular injection of one of these extracts in a dosage of 2 to 4 c.c. daily for the first 3 days. The interval between doses is gradually increased to a week or 10 days, and finally a maintenance dose is determined, which will usually vary from 4 to 6 c.c. at intervals of 3 to 6 weeks. In very severe cases treatment may begin with a single injection of 5 c.c. of an intravenous extract, or 4 c.c. of an intramuscular extract every 6 hours for the first 24 hours. Desiccated stomach or oral extracts of liver may be given by mouth when treatment by injections is inconvenient. The usual dose of desiccated stomach is ½ oz. twice daily. Fluid extracts of liver are more palatable than dry, and they should be given in a dose equivalent to from ½ lb. to 2 lb. of liver a day. When a patient

comes under treatment for subacute combined degeneration, recovery may be accelerated by a course of massive liver therapy, 4 to 8 c.c. of an intramuscular extract daily for 6 weeks. I am convinced that subacute combined degeneration can be prevented, and that its progress in the early stages can be arrested by adequate treatment. It has been well said that the daily maintenance dose is " not some liver, but enough liver for the given case." The blood should be kept at 5 million red cells per c.mm., and 100 per cent. of hæmoglobin, and it should be examined at intervals to ensure that this level is maintained. Patients should be told that treatment must be continued for the rest of their lives and they should also be warned of the folly of relaxing treatment. The disappearance of macrocytosis is probably the most reliable laboratory test that treatment is adequate. Whatever the level of the blood count, paræsthesiæ or similar nervous symptoms suggest that enough effective substance is not being given. Infections and old age both increase the dosage necessary for the control of pernicious anæmia.

Hydrochloric acid is of value in the treatment of the dyspepsia of simple achlorhydric and pernicious anæmia, but it has no effect on the anæmia. Heroic doses are unnecessary, 20 to 30 minims of the dilute acid at mealtime being sufficient. If desiccated stomach is employed, hydrochloric acid is not usually required.

Arsenic is a drug which was formerly administered in all forms of anæmia, but its use is now becoming restricted to leukæmia and erythræmia. It is usually given as liquor arsenicalis, beginning with 2 minims and increasing to 10 to 15 minims thrice daily, after meals, until the desired effect is produced, or signs of intoxication begin to appear. The drug is then discontinued for 4 to 6 days, and resumed in a smaller daily dosage, the maintenance dose being determined by the clinical condition and the blood picture.

X-rays and to a less extent *radium* are employed in two ways in diseases of the blood-forming organs : in small doses as a stimulant, and in large doses as a depressant. Stimulating doses are used in agranulocytosis and in purpura hæmorrhagica, but this form of treatment can hardly be said to have established itself yet. Depressant doses are employed in leukæmia and polycythæmia : the rays may be applied to the bones, to the spleen or to enlarged glands. The best results appear to be obtained with small doses frequently repeated. In leukæmia treatment is stopped when the white count has fallen to about 15,000, as the fall may continue for 2 or 3 weeks after cessation of treatment ; it should be resumed whenever the white count rises above 50,000 cells per c.mm.

Transfusion is essentially an emergency measure, and it has little curative value except in the rare hæmolytic anæmia of Lederer. It has a definite mortality, and should be advised with as much circumspection as a surgical operation. It is indicated when the patient is too ill to react to curative treatment, or when it is necessary to bring him into condition for treatment directed at the cause of the anæmia. The very greatest care should be taken, fresh sera always being employed for the grouping, and a direct compatibility test being carried out immediately before transfusion. Donor and recipient should always belong to the same group, for experience has shown that members of group O cannot safely be employed as universal donors. Under ordinary conditions the advantages of working with citrated

blood outweigh any theoretical disadvantages; the blood should be kept warm and should be administered slowly. Even when every care is taken reactions occur, especially in febrile patients. The anaphylactic type of reaction occurs during or immediately after the transfusion. It is characterised by dyspnœa, cyanosis, swelling of the face, and urticarial rashes, and it responds to treatment by adrenaline or morphine. The hæmolytic type of reaction may occur during the transfusion, or some hours later. It is characterised by tingling pains in the veins, præcordial oppression, cyanosis, rigors, high fever, hæmoglobinuria and jaundice; death may occur at once, or later from suppression of urine. It has been shown that suppression of urine will not occur if the urine is dilute and alkaline, and it is therefore advisable to prescribe fluid and alkalis for 24 hours before and after a transfusion. A single transfusion of a pint of blood raises the hæmoglobin on an average about 10 per cent. This is rarely sufficient for patients who are severely collapsed and anæmic, as after a bad hæmatemesis, and in such cases a cannula may be tied into a vein and 2 or 3 litres of blood may be slowly introduced at a rate of 90 to 150 c.c. an hour.

L J. Witts.

SECTION XI

DISEASES OF THE SPLEEN AND THE RETICULO-ENDOTHELIAL SYSTEM

INTRODUCTION

The spleen is a composite organ made up of various tissues which are also found elsewhere in the body. Any individual tissue, not only in the spleen but wherever else it occurs, may be simultaneously attacked by disease. Thus, the *classification* of diseases of the spleen is difficult, because few of the diseases are confined to this one organ, and many are fully described, in their clinical aspects, in other sections of this volume.

In order to understand some of the difficult and, in many ways, still anomalous diseases of the spleen, it is essential to consider briefly the structure and functions of the organ. An important general point is the essential "lobularity" of the spleen, which explains the features of many pathological conditions (*e.g.* infarctions) and abnormalities.

The tissues which make up the human spleen are:

1. The Hæmopoietic or Blood-forming Tissues.—In the fœtus the liver and spleen are the chief blood-forming organs. In post-natal life the bone-marrow takes over this function, which, however, can be called into great activity again in both the liver and the spleen in a number of blood diseases.

2. The Lymphoid Tissues.—These are found in the spleen as the Malpighian bodies, and elsewhere as the lymph nodes and collections of lymphoid tissue scattered widely through the body.

3. The Reticulo-Endothelial Tissues.—The cells of this tissue line the splenic blood sinuses, and occur abundantly in the pulp. Elsewhere they are met with as the Kupffer cells of the liver, in the bone-marrow, in the lymph glands and in other situations.

4. The Vascular Structures.—These are peculiar, and are described subsequently. The spleen is in direct connection with the portal venous system and, of necessity, is involved in many diseases and abnormalities of that system. This fact, together with others already mentioned, bring the liver and spleen into close relationship in disease.

5. The Supporting Tissues.—These consist of the capsule, the trabeculæ, and the reticulum of the pulp.

A diagrammatic sketch of a splenic lobule is provided (Fig. 19). It may require modification or correction in future, but without some such scheme in mind, it is difficult to correlate structure with functions, and to explain the reactions of different parts of the spleen in disease.

Functions.—It has long been known that the spleen, by itself, performs

no function essential for life, and that the organ can be removed without permanent harm to the individual. The functions of the spleen are those of its component parts, and nothing need be said here of splenic functions in relation to the hæmopoietic and lymphatic systems, as these are dealt with elsewhere. The activities of two structural parts, namely, (1) the spleen as part of the Reticulo-Endothelial System, and (2) the spleen as a blood reservoir, require more detailed consideration.

1. The Spleen as part of the Reticulo-Endothelial System.—The spleen contains the largest collection of cells of this system in the body, and is necessarily involved in all diseases in which these cells react. Some diseases, particularly affecting the reticulo-endothelial system, are, for the sake of clarity, dealt with separately (p. 833), and it is important to summarise the main functions of the spleen as part of the reticulo-endothelial system. These are :

(*a*) *Phagocytosis.*—This is a most active splenic function, resulting in the destruction of bacteria, protozoa and red blood corpuscles. This "filtering out" activity at once brings to mind the splenic changes in infections (typhoid fever, malaria), and the enlargement of the organ in hæmolytic anæmias (pernicious anæmia, acholuric jaundice).

(*b*) *Storage.*—These cells of the reticulo-endothelial system play an important part in the intermediate metabolism and storage of fats, lipoids, hæmoglobin and iron. These functions are referred to in greater detail in connection with Gaucher's and other diseases.

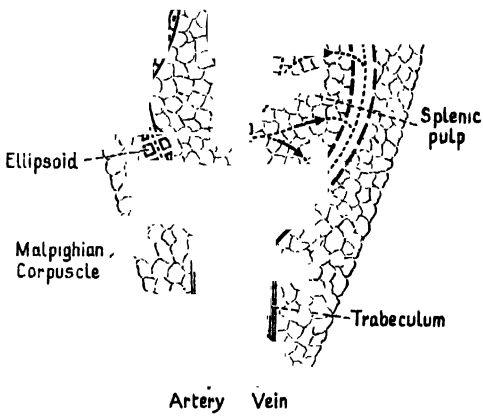

Fig. 19.—Diagrammatic sketch of a splenic lobule.

(*c*) *Formation of blood cells.*—Cells of this system (monocytes) enter the blood stream, and alter the blood picture in a number of diseases.

(*d*) *Development of immunity reactions.*—One such reaction is the phagocytosis of invading micro-organisms, referred to previously. Much work has also been done suggesting that the reticulo-endothelial cells are the main source of antibodies, antitoxins, precipitins and agglutinins. It is certain that in chronic infective diseases these cells most abundantly react and proliferate (*e.g.* the giant cells and histiocytes of tuberculosis and syphilis). Some hitherto unexplainable examples of splenomegaly (reticulo-endotheliosis of the spleen) may come into this category.

2. The Spleen as a Blood Reservoir.—The contractility of the spleen has long been recognised, but its significance was not appreciated. It enables an extra supply of blood to be suddenly withdrawn from the organ and poured into the general circulation in bodily emergencies—hæmorrhage,

exercise, emotion. Study of this function involved an inquiry as to how blood is stored in the spleen, and this not only emphasised the peculiar vascular arrangements and structures of the organ but also explained, in part at least, some well-known pathological changes in enlargement of the spleen which previously were puzzling.

No hypothesis of the mechanism of the splenic circulation fits the facts so well as the " two-way " blood flow through the organ suggested in Fig. 19. Taking this view, blood normally flows through the splenic artery, arterioles and blood sinuses, to return at once through the veins. Some blood is, however, deflected in order to be stored in the spongy pulp among the reticulo-endothelial cells, and ready to be restored at once to the venous outflow on contraction of the spleen. Blood reaches the pulp through the walls of the " ellipsoids," and a short description of these structures, which are peculiar to the spleen, is essential.

Ellipsoids are thickenings of reticulo-endothelial tissue surrounding the terminations of the fine " penicillar " arterioles. They act potentially as valves, and through channels in their loosely formed walls blood-cells reach the pulp. It is at or about the ellipsoids that perivascular hæmorrhages, with their peculiar end-result referred to subsequently, occur so commonly in many forms of splenomegaly.

It is evident, judging from clinical results in purpura hæmorrhagica (p. 810), that the spleen must have some important influence on blood-platelet formation or destruction, but the mechanism is not understood.

Another fact concerning the spleen, difficult to explain but well recognised clinically, is the apparent resistance of the splenic tissues to tumour growth.

A. DISEASES OF THE SPLEEN

ABNORMALITIES OF THE SPLEEN

The spleen may be completely absent, or may take the form of small spleniculi (syn. splenunculi, accessory spleens) scattered throughout the upper abdomen. A few small accessory spleens, in close proximity to an otherwise normal spleen, are quite common, and share in all pathological processes of the main organ.

Congenital lobulation is occasionally found, and emphasises the essential lobular structure. Normally only the characteristic notch or notches on the anterior border persist as evidence of this fact.

FLOATING SPLEEN

Synonyms.—Wandering Spleen; Movable Spleen; Dislocation of the Spleen.

Ætiology.—This condition occurs almost exclusively in females, and may either form part of a general visceroptosis or follow enlargement of the organ from disease. Trauma may be a direct ætiological factor, especially when the spleen is enlarged, and dislocation may occur quite suddenly. The question

of whether supporting ligaments are torn or only stretched has been much disputed.

Pathology.—A floating or dislocated spleen has been found in almost every part of the abdomen, even in the pelvis. Perisplenitis generally supervenes, and the organ becomes fixed in position. If diseased, the organ may continue to enlarge in its new location.

Symptoms.—Apart from those caused by complications, the symptoms may be very indefinite, and consist chiefly of localised pain from perisplenitis, and the effects of pressure on adjacent organs or on the intestine.

Certain complications may arise. Prior to fixation, acute twisting of the pedicle may lead to abdominal symptoms resembling those following twisting of the pedicle of an ovarian cyst. Slower torsion of the pedicle leads to simple atrophy, without symptoms. A number of other rare abdominal complications, due to traction on abdominal viscera, have been described.

Diagnosis.—This depends on the discovery by abdominal palpation that the spleen is absent from its normal position (although clinical proof of this is difficult), and of the presence of a tumour. Diagnosis may be easy if the characteristic shape and notches can be felt through a lax abdominal wall. If, however, the organ is fixed, carcinoma may be closely simulated. Examination under an anæsthetic may afford help, but often a correct diagnosis is only made by laparotomy.

Treatment.—Splenectomy is to be recommended in the majority of cases.

INFARCTION OF THE SPLEEN

Infarction of the spleen may be aseptic or septic. *Total aseptic infarction* is probably commoner than is supposed, especially in cardiac disease. It does not give rise to symptoms, and may be found accidentally at necropsy. *Total septic infarction* is very rare, but may lead to abscess formation. *Partial infarction* or *multiple infarctions*, both aseptic and septic, are common in a great variety of diseases. Apart from local treatment for pain, they generally require little attention, unless abscess supervenes.

ABSCESS OF THE SPLEEN

This may be single, but is more often multiple and the sequel to multiple septic infarctions. It occurs in typhoid fever, phlebitis, erysipelas and other infective conditions, and is dangerous because it so often escapes detection until rupture and peritonitis ensue. The diagnostic signs—which, however, are not confined to this disease—are sudden pain, tenderness and acute perisplenitis with an audible friction rub.

RUPTURE OF THE SPLEEN

Ætiology.—Rupture of the spleen may occur in a healthy individual as the result of injury, but is more common when the organ is enlarged and diseased. The first is chiefly of interest to surgeons. The second (sometimes

called " spontaneous rupture ") is of much importance to the physician and also in medico-legal work. Spontaneous rupture may take place in acute infective diseases (*e.g.* typhoid fever), in chronic infections (*e.g.* malaria), in leukæmia, and in other varieties of splenomegaly. In all of these the splenic capsule is altered by inflammation, by distension, by disease, or by a combination of these conditions. When a spleen has undergone great and rapid enlargement from any cause the danger is particularly severe, and too robust clinical examination of a leukæmic spleen has resulted in rupture of the thin and stretched capsule. Trauma, to cause rupture of an acutely enlarged spleen, may in fact be so slight as to escape notice, and may be very indirect in its application.

Pathology.—The rupture may occur in any part of the organ, and the tears may be longitudinal or transverse, single or multiple. As a rule, both the capsule and splenic tissues are torn, but " delayed rupture " may ensue when the splenic tissues are only bruised, and a collection of blood finally bursts through the capsule.

Symptoms and Diagnosis.—In most cases the patient experiences sudden violent pain in the region of the spleen, followed almost immediately by dizziness and collapse. The clinical picture is soon simply that of a severe internal hæmorrhage, and if the patient is unconscious an accurate diagnosis may be impossible in the absence of a previous medical history.

Prognosis.—This is improving with the advances in emergency surgery, but is still very serious, especially in conditions of actual splenic disease.

Treatment.—This is surgical.

SEPTIC SPLEEN

Synonym.—Acute Splenic Tumour.

This condition is an accompaniment of a great variety of infective diseases, and the recognition of splenic enlargement may be important in the general diagnostic picture (*e.g.* typhoid fever, infective endocarditis, abortus fever). Pathologists divide septic spleens into two types—the " red " spleen, most characteristically seen in typhoid fever; and the " grey " spleen, common in pneumonia, infective endocarditis, and in most septic conditions.

In the recognition of slight splenic enlargement, percussion is difficult and far less trustworthy than palpation of the tip of the organ below the ribs. It should be remembered that the spleen may be felt in various situations below the left costal margin, sometimes nearer the xiphisternum and sometimes in the extreme flank. Palpation is easier in an individual with a broad chest and wide costal angle than in the opposite type.

CHRONIC VENOUS CONGESTION OF THE SPLEEN

This occurs in congestive heart failure, but is of no clinical significance, and the spleen is seldom obviously enlarged during life. In portal hepatic cirrhosis, enlargement may be very considerable and form a real splenomegaly. It is tempting to suggest that the enlargement is due simply to back-pressure and congestion of the portal venous system, but all attempts to bring about chronic

splenic enlargement experimentally in this manner have been a signal failure. The considerable splenomegaly noted in some cases of hepatic cirrhosis must therefore be due to some unknown factor or factors.

CYSTS OF THE SPLEEN

Three varieties of cysts of the spleen have been described, namely, dermoid, echinococcus (hydatid) and serous or hæmorrhagic. All are uncommon. *Serous* or *hæmorrhagic cysts* will alone be dealt with.

Ætiology.—It has been claimed that this variety of cyst is congenital, and also that it may follow injury. The exact facts, however, are unknown, but when once formed they continue to grow slowly and indefinitely.

Pathology.—Serous or hæmorrhagic cysts may be single or multiple. They contain a mixture of fluid and light chocolate-coloured debris, with abundant cholesterol crystals producing a distinct sheen. Perisplenitis is common, but rupture is rare. A cyst may be deep within the splenic tissues, or may project backwards.

Symptoms.—The cysts may be large enough to bring about splenomegaly. If they project backwards, a thinned-out but apparently normal anterior margin, with the characteristic notches, may be felt through the abdominal wall and simulate other forms of splenomegaly.

The only pathognomonic sign is fluctuation, but even when this is detected the diagnosis from congenital cystic kidney may require to be made. Repeated attacks of acute perisplenitis are a noteworthy feature.

Treatment.—Splenectomy should be performed as early as possible, before dense perisplenitic adhesions have formed.

PERISPLENITIS

Perisplenitis, or inflammation of the splenic capsule, is mentioned in connection with a great many acute and chronic diseases, and is of considerable clinical importance. When acute, there is generally associated pain. Perisplenitis may be detected either by manual palpation or frequently only by the aid of the stethoscope over the tender area. It may, when acute, as already indicated, be of real diagnostic importance, while in the chronic stages it may present a serious problem to the surgeon and hinder or prevent successful splenectomy. Dense perisplenitic adhesions between the upper pole of the spleen and the vault of the diaphragm are the gravest danger in the technique of splenic surgery. Perisplenitis over the anterior surface of the spleen, even when of long duration, seldom gives rise to adhesions, and may show the same " sugar-iced " appearance as in Pick's disease.

CHRONIC ENLARGEMENT OF THE SPLEEN

Synonym.—Splenomegaly.

Chronic splenic enlargement may be simulated by: (1) Tumours, enlargements and displacements of the left kidney. (2) A greatly enlarged

left lobe of the liver. (3) A rolled-up carcinomatous or tuberculous omentum. (4) Carcinoma of the splenic flexure of the colon. (5) Carcinoma of the body of the stomach. If these can be excluded, then a mass felt in the left upper abdomen is almost certainly an enlarged spleen.

In this section only the chronic enlargements of the spleen not dealt with elsewhere will be considered. Splenomegaly is a feature of many diseases, both in the tropics and in temperate climates. Mention may be made of a few examples—malaria, kala-azar, schistosomiasis (including Egyptian splenomegaly), anæmias, leukæmias, tuberculosis, syphilis and Hodgkin's disease.

The composite structure of the spleen in relation to the pathology of many of the above diseases is discussed elsewhere.

In most splenic enlargements, as chronicity increases, changes occur in the trabeculæ and reticulum, which become thickened, and the whole spleen becomes dense and fibrous.

Changes in the vascular system are common in splenomegaly, and are of such peculiar type as to require description.

Vascular changes in splenomegaly.—These are of two main types:

1. Thrombosis, often followed by tunnelling of the organised thrombus so as partially to restore the circulation of the main splenic vein or even of the portal vein. This thrombo-phlebitic lesion, to which particular attention was drawn by Warthin, is found at necropsy in a number of patients who have suffered from long-standing splenomegaly. The splenic enlargement may be enormous; hepatic cirrhosis and ascites are common in the late stages; and clinically it is impossible to separate this type of splenomegaly from that shortly to be described as "splenic anæmia." The exact cause and significance of "thrombo-phlebitic splenomegaly" are not understood, but the condition may be simply a complication of the more ordinary type of splenic anæmia.

2. "Fibro-siderotic nodules," due to organisation of perivascular hæmorrhages in the neighbourhood of the ellipsoids. This lesion, which appears to be entirely non-specific, may be present or absent in almost any form of splenic enlargement. It is often particularly well seen in chronic "splenic anæmia," but may be found abundantly in the spleen removed from a child suffering from acholuric jaundice. In a cut section of the spleen the nodules present a striking appearance as small firm yellowish-brown nodules, standing out from the surface, and aptly compared to "flakes of tobacco-leaf." Originally described by Stengel, they have recently attracted much attention under the name "Gandy-Gamna bodies." It was claimed that they were evidence of a streptothrix infection invading the spleen and the cause of the splenomegaly, but this view is now given up. How they arise is uncertain, but they are readily recognised to be the result of organisation of a hæmorrhage round a small arteriole, and consist of fibroblasts, crystals of iron phosphate, and phagocytic cells containing abundant golden-yellow hæmosiderin.

SPLENIC ANÆMIA

Synonym.—Hepato-lienal Fibrosis. *Old synonyms:* Banti's disease; Banti's syndrome.

Splenic anæmia is the most common, and also the most difficult, form of chronic splenomegaly met with in this country. There has been much trouble with nomenclature, much difficulty in interpreting the splenic histology, and much discussion as to whether we are dealing merely with a clinical syndrome or a true pathological entity. Originally described as "anæmia splenica" (1866), and as "splenic pseudo-leukæmia" in the days before the pathology of the leukæmias was understood, the name "splenic anæmia" was again brought into clinical use by Osler (1902). Confusion has always been rife over the relations of the disease first described by Banti in 1883, and amplified in subsequent descriptions by him up to 1910. It may be said at once that the *clinical* phenomena in splenic anæmia and Banti's disease are identical in all respects. Argument has centred round the problem of Banti's somewhat varied description of the pathology of the spleen in his cases, and whether the changes described by him are peculiar and diagnostic of a distinct pathological entity, rarely if ever found elsewhere. The matter is now of no clinical importance unless or until a definite ætiological cause for this common type of splenomegaly is discovered, but to avoid confusion it would be better if the term "Banti's disease" were omitted altogether from clinical use, and the older term "splenic anæmia" retained. The synonym "hepato-lienal fibrosis" is an attempt to indicate the main gross pathological changes characteristic of this syndrome or disease.

Definition. — A chronic disease or syndrome characterised by splenomegaly, moderate anæmia of the hypochromic type with low colour-index, leucopenia, and a tendency to hæmorrhage, especially from the stomach. The terminal stage is associated with hepatic cirrhosis, jaundice and ascites.

Ætiology.—This is unknown. It is usually stated that the splenic changes appear first, and the hepatic fibrosis subsequently. Heredity plays no part. The condition is generally held to be more common in males than females, but in a personal series of 45 cases, 22 were males and 23 females. It is a very chronic disease, probably never recognised at its outset, but the first symptoms often appear (25 out of 45 cases) before the age of 30 years.

Pathology.—The characteristic histological changes in the spleen may be briefly summed up as peri-arterial hæmorrhages (some of which may develop into fibro-siderotic nodules); dilatation of the blood sinuses; proliferation of histiocytic (reticulo-endothelial) cells around the sinuses and in the pulp; and generalised fibrosis of the trabeculæ and reticulum. The Malpighian bodies also share in the fibrosis. The liver changes vary greatly in degree; the earlier changes are little known, but the later stages differ in no way from those of ordinary hepatic cirrhosis. There are no other primary pathological changes of importance.

Symptoms.—Splenomegaly is essential, but its degree varies. The average weight in a series of cases was about 900 g., though the weight may be as much as 3000 g. The spleen feels smooth, firm and uniform. Moderate anæmia is the rule, unless the case is complicated by recent hæmorrhage. An average red cell count is perhaps 2 to 3 millions per c.mm. or more; hæmoglobin 30 to 50 per cent., and the colour-index always below unity. The leucocytes are diminished, being seldom over 5000 per c.mm., and a common average count is 2 to 3000 per c.mm. There are no characteristic features in stained films.

Hæmorrhage from the stomach (derived especially from large veins passing in the gastro-splenic omentum "vasa brevia" or occasionally from œsophageal veins in the late stages of the disease) occurs in a large percentage of cases, and may be copious and repeated. More rarely, intestinal bleeding occurs, or the skin may show purpura simplex. The skin is generally light yellow in tint, but brownish pigmentation is not uncommon.

The terminal stage of the disease is identical with that of ordinary hepatic cirrhosis, with signs of portal obstruction, ascites and jaundice.

Course.—This is chronic, the duration varying from several to many years, and in the majority from 5 to 12 years.

Diagnosis.—The diagnosis is made merely by a process of exclusion after considering all other forms of chronic splenomegaly. The spleen is larger than in most cases of ordinary hepatic cirrhosis. The association of anæmia and leucopenia is important.

Prognosis.—This is invariably bad, but greatly depends on the onset of complications, such as hæmorrhage, hepatic cirrhosis, ascites and possibly thrombosis of the splenic or portal vein. Most patients die from hæmorrhage or hepatic insufficiency, but a few simply from asthenia.

Treatment.—This remains unsatisfactory, since the ætiology is unknown. The constant hypochromic anæmia has received insufficient attention in the past, and in the absence of actual hæmorrhage it is generally possible by intensive iron therapy to raise the hæmoglobin percentage considerably, with great improvement to health. After severe hæmatemesis blood transfusion may be required.

Apart from this general treatment, splenectomy has been the chief therapeutic measure recommended, based on the view that the changes in the spleen, whatever their origin, occur first and later influence changes in the liver. This hypothesis is by no means universally held, and some maintain that the course of this chronic disease is unaltered by splenectomy at any stage. It is certainly true that splenectomy does not prevent the occurrence of severe and even fatal hæmatemesis, which has been met with several years afterwards. On the other hand, striking improvement has been obtained even in late and unpromising cases with ascites. It is clear, moreover, that some of the failures of splenectomy must now be set down to errors in diagnosis, since the differentiation of diseases such as leuco-erythroblastic anæmia (p. 783) is comparatively recent. On the whole, while opinion remains divided through lack of positive knowledge, both of ætiology and progress, splenectomy should be reserved for cases in which reasonable health is not being maintained in spite of active treatment of the anæmia. Enormous splenomegaly or repeated attacks of perisplenitis are other indications for surgery. If splenectomy be decided upon, the blood platelet count should be carefully watched (as in every operation of splenectomy), and, if the count is high, the operation should be deferred. A rise in the platelet count occurs after splenectomy, and if figures of 750,000 or more per c.mm. are reached, there is some danger of widespread and even fatal thrombosis in abdominal veins or elsewhere.

The alternative to splenectomy is X-ray treatment applied over the spleen, which may reduce the size of the organ, but does not influence the course of the disease.

TUBERCULOSIS OF THE SPLEEN

Although the spleen shows tubercles in almost every fatal case of tuberculosis, localised infection leading to chronic splenomegaly is rare. This does occur, however, and the splenic enlargement, which may be considerable, presents a difficult problem in diagnosis. The true pathology is seldom suspected, unless active tuberculosis is known to exist in other organs. In such circumstances, however, an amyloid spleen might first be suspected. The treatment must obviously vary in relation to the presence and course of tuberculosis elsewhere, but massive tuberculosis of the spleen should be regarded as dangerous and splenectomy is indicated.

TUMOURS OF THE SPLEEN

Simple tumours are very rare, but fibromas, hæmangiomas and lymphangiomas have been noted.

Sarcoma is the only primary malignant tumour. Primary carcinoma of the spleen, because of the absence of epithelial tissue, cannot exist, and the rarity even of secondary carcinoma has been commented upon.

Sarcoma is of two types—one diffuse and the other arising in, and producing great enlargement of, the Malpighian bodies. There may be great difficulty in deciding whether true tumour growth exists, or merely excessive proliferation of reticulo-endothelial cells. Secondary nodules in lymphatic glands may afford the only proof. Diagnosis is impossible without laparotomy. Splenectomy should be carried out, and cases of permanent cure are on record.

B. DISEASES OF THE RETICULO-ENDOTHELIAL SYSTEM

The position of the cells of the reticulo-endothelial system within the body and the main functions attributed to them have already been discussed. Some confusion often arises because different terms are applied to the cells of this system, and it may be well to mention that monocytes, histiocytes, macrophages, endothelial cells and large mononuclear cells may all belong to this group, the cells being derived from reticular cells and from endothelium.

The following diseases, not described elsewhere and associated with hypertrophy of this system of cells, are recognised :

MONOCYTIC LEUKÆMIA

A variety of acute leukæmia only recently identified, and not easy to separate from the acute myeloblastic type (see p. 802).

HYPERCHOLESTEROLÆMIC SPLENOMEGALY IN DIABETES MELLITUS

This is a rare condition, arising in conjunction with lipæmia in the blood. The enlarged spleen is filled with foamy cells containing lipoid, which, however, may not show double refraction to light when viewed through crossed Nicol's prisms, as does ordinary cholesterol-ester. For this reason, confusion with Gaucher's disease may easily arise. Chemical analysis, however, proves the presence in the tissue of a great excess of cholesterol. These cases clinically often exhibit xanthomatosis of the skin, and some have shown the interesting complication of hepatic cirrhosis and jaundice.

XANTHOMATOSIS. (See p. 1468.)

SARCOIDOSIS. (See p. 1467.)

GAUCHER'S DISEASE

Definition.—An uncommon chronic disease, arising in early life and first characterised clinically by progressive splenic enlargement; hepatic enlargement soon follows the splenomegaly; and, finally, the two organs are enormous. The condition is due to a peculiar type of reticulo-endothelial hyperplasia, in which the cells (in spleen, liver, bone-marrow and elsewhere) are filled with a lipoid substance named kerasin.

Ætiology.—This is unknown, but it is possible that the condition is due to an inborn error of metabolism. The disease begins very insidiously in early life. Most cases are recognised before 10 years of age, but in a few, only in adult life. In a well-known published series, females outnumber males as much as 7 to 1. The Jewish race exhibits a special proclivity to this disease, but it is found in other races. Familial incidence is important, as affording some evidence of an inherited abnormality. As many as four children in a single generation of one family have suffered from the disease.

Pathology.—The reticulo-endothelial cells, wherever they occur, become enormously distended with " kerasin," which is not doubly refractive to light. In paraffin sections the large foamy cells are very characteristic. The spleen, and later the liver, are grossly enlarged and smooth, and large collections of the cells in the bone-marrow may ultimately lead to spontaneous fractures. (See p. 1392).

Symptoms.—Slowly progressing splenic enlargement is the first and cardinal sign. The enlargement soon forms a distinct bulge on the left side of the abdomen, and ultimately is enormous. This is followed later by enlargement of the liver. Ultimately the two organs may be so enormous as to appear to fill the whole abdomen. The lymph glands are never enlarged. The eyes show a phenomenon which is so constant as to be almost pathognomonic: a brownish-yellow wedge-shaped thickening, or pinguecula, appears first on the nasal, and later on the temporal, side of each eye. The skin of the face, neck, forearms and hands frequently shows a peculiar brownish-

yellow solid pigmentation, or mottling, which may also be seen over both legs and ankles. The pigment does not appear to be hæmosiderin. Hæmorrhage from mucous membranes (epistaxis, bleeding from the gums) is common, but never severe. Small hæmorrhages and hæmorrhagic pimples are frequent in the skin, particularly in areas liable to slight trauma. There are no characteristic changes in the blood, and anæmia is absent except in the very late stages. Apart from the inconvenience due to the enormous abdominal distension, the patients may complain little, and the mental faculties are unimpaired.

Course and Termination.—The disease is very chronic, but exhibits a slow and progressive advance. Cases are on record of over 40 years' duration, and of 20 years after splenectomy in adult life. Death often ensues from some intercurrent disease.

Diagnosis.—The familial history; early onset; great and progressive splenomegaly; hepatic enlargement; changes in the eyes; pigmentation; and great chronicity—these constituting an almost characteristic and unmistakable picture. Von Gierke's disease (Glycogen disease) (p. 692) is distinguished by the great hepatic enlargement, together with an absence of splenomegaly.

Treatment.—Splenectomy is to be recommended, in childhood if possible. Even if cure cannot be promised, the patient is relieved from the enormous subsequent abdominal distension.

NIEMANN-PICK'S DISEASE

Synonym.—Pick-Niemann's Disease.

Definition.—A rare more or less generalised disease of the reticulo-endothelial system, confined to infancy or very early childhood and rapidly fatal. First described by Niemann (1914) and Pick (1924), the affected cells are filled with a peculiar complex lipoid. At least 50 per cent. of the patients are of Jewish stock, and although a review of most of the recorded cases shows that there is some familial tendency, this is not very striking.

Pathology.—Reticulo-endothelial cells, wherever they occur, are filled with a complex lipoid mainly composed of phosphatides. The liver, spleen and to a less extent the lymph glands are in consequence enlarged. Histological examination also reveals the presence of many foamy cells containing the lipoid in the bone-marrow and elsewhere. The blood picture is normal.

Symptoms.—The disease begins in the first year, the infant does not thrive, and the exposed skin shows a brownish pigmentation. A mongoloid facies is occasionally noticed. The liver and spleen rapidly enlarge, and may soon almost fill the distended abdomen. Groups of lymphatic glands are also swollen.

Diagnosis.—Confusion may arise with: (1) Waren Tay-Sachs' Disease (Amaurotic Family Idiocy), a disease of infants, strongly familial, almost always affecting the Jewish race, and due to a lipoid degeneration of cells of the central nervous system. In this malady, however, the liver and spleen are not enlarged. (2) Gaucher's Disease. This begins later in childhood and persists into adult life. (3) Von Jaksch's Anæmia. This is at once

differentiated by the blood picture. (4) Congenital Syphilis with hepatic enlargement.

Prognosis and Treatment.—Death occurs almost invariably within two years of birth, and no treatment is possible.

HAND-SCHÜLLER-CHRISTIAN'S DISEASE

Synonyms.—Hand's Disease; Schüller-Christian's Disease or Syndrome.

Definition.—This is a rare lipoid disturbance of the reticulo-endothelial cells, but it is of greater importance than Niemann-Pick's disease because some sufferers survive to adult life. First described by Hand in 1893, cases were also recorded by Schüller in 1915 and Christian in 1919; in all, over one hundred have been reported.

Ætiology.—This is quite unknown. There is no hereditary, family or racial tendency, and either sex may be affected. The disease usually first shows itself in early childhood, but occasionally somewhat later. Mental changes are absent.

Pathology.—The diagnostic feature is the presence of localised deposits of cholesterol-ester in the bones of the skull, most easily recognised in the flat bones of the vault but also occurring elsewhere. Other bones of the body are rarely involved (see p. 1393). Histologically the lipoid is contained in "foamy" cells, and giant cells are numerous. The lesion, in fact, closely resembles xanthoma (p. 1468), and the clinical features of the disease under discussion are due to the peculiar and characteristic sites of the lipoid deposit. The cholesterol content of the blood is often, but by no means invariably, raised.

Symptoms.—The three outstanding features of the disease are: (1) Bony defects of the skull, visible as areas of decreased density in X-ray films; (2) diabetes insipidus, due to localised involvement of the pituitary; and (3) exophthalmos, on one or both sides.

The clinical signs which usually first attract attention in a child are diabetes insipidus or exophthalmos; the former is present in 70 per cent. of all cases, the latter not so frequently. When X-ray films are taken defects in the skull are invariably visible.

Diagnosis.—The three points mentioned above are characteristic. The changes in the skull, seen by X-rays, are essential; but the diagnosis may still be made when one or even both of the others are absent. Various clinical features have been described in individual cases, but none of these form an essential part of the syndrome or aid diagnosis.

Prognosis.—This is not good, and one third of the patients die in childhood. The earlier the onset (before 5 years) the worse the outlook. The initial acute phase is evidently the danger. If the patient survives this and the chronic stage (presenting itself chiefly as diabetes insipidus) is reached, he may live for many years.

Treatment.—X-ray therapy may benefit the local condition in the bones of the skull, and should be tried. Dietetic restriction of foods rich in cholesterol has been recommended, but is of doubtful value. No treatment is known to remove the exophthalmos, but the diabetes insipidus responds quite well to the usual therapy for that disease (p. 483).

RETICULO-ENDOTHELIOSIS OF THE SPLEEN

Here may be mentioned a number of cases of chronic splenomegaly, often with enormous enlargement, and of unknown ætiology. The clinical picture resembles splenic anæmia, but on histological examination the organ exhibits extreme reticulo-endothelial hyperplasia, and frequently giant-cells are present. In some cases the liver has been found to be cirrhosed. The exact status of this group of cases is still undetermined, but the histological changes in the spleen are quite unlike Hodgkin's disease, or any other type of splenomegaly.

J. W. McNee.

SECTION XII

DISEASES OF THE LYMPHATIC SYSTEM

INTRODUCTION

THE lymphatic system consists of the lymphatic vessels (lymphatics), the thoracic duct, the lymph nodes or glands, and multitudes of large or small collections of lymphoid cells scattered throughout almost every organ and tissue of the body. Examples of large collections are the tonsils, the Peyer's patches of the intestine, the Malpighian bodies of the spleen, and the thymus gland. Small collections are well seen in the liver, the bone-marrow, the lungs, the thyroid gland, and in many other situations.

Our knowledge of the functions of this abundant tissue is still meagre. It seems certain that the larger collections of lymphoid tissue, and especially the lymph nodes, may be regarded as filters of the blood plasma. How is this function carried out? It is now recognised that the lymph nodes are not made up merely of lymphocytes and lymph-follicles, but contain both lymphoid and reticulo-endothelial tissue. The sinuses of the lymph glands are lined by reticulo-endothelium, through which all substances entering the glands must pass. The functions of the reticulo-endothelial cells have already been discussed (p. 824), and it is this part of the lymph gland which is believed to filter out, or store, foreign particles, bacteria, and metabolic products. As a result, the gland may often be damaged or diseased.

A lymph gland is arranged in follicles, and it was long claimed that the centre of each follicle, which contains pale and larger cells, is the "germinal centre" in which new lymphocytes, large and small, are formed. It is now considered more probable (although still unproved) that the large pale central cells are essentially reticulo-endothelial in function.

The purely lymphoid parts of the glands are the source of the lymphocytes, but the functions subserved by these cells, in the blood stream and elsewhere, are still unknown.

The thymus gland is also double in structure, the larger cortical part being chiefly composed of ordinary lymphoid tissue, while the smaller medulla (Hassall's corpuscles) is epithelial in origin.

DISEASES OF THE LYMPHATIC VESSELS

(i) DISEASES OF THE THORACIC DUCT

Apart from obstruction of the duct, caused by intrinsic or extrinsic tumours (usually malignant in nature), and less often by tuberculosis, aneurysm and lymphadenoma, lesions in this situation are rare and are very difficult of

recognition during life. The results of obstruction are chylous pleural effusion and (or) chylous ascites. Since chyliform ascites may occur without obstruction to the thoracic duct, as in tuberculous peritonitis, peritoneal carcinomatosis and even in cirrhosis of the liver, the presence of a milky pleural effusion is better evidence of a thoracic duct lesion than is a milky ascites. But even here the diagnosis is by no means certain on this fact alone. Chyluria, with chylous œdema of the genitals and lower extremities, if concurring with one or both of the above do, however, make diagnosis of obstruction to the thoracic duct almost certain.

(ii) DISEASES OF THE LYMPHATIC VESSELS

(i) LYMPHANGITIS.—Acute inflammation of the smaller lymphatics is a very common infection, and is mainly of surgical significance. When present in septicæmia, however, its importance lies in the fact that it indicates the area of primary septic infection, or that pyæmic metastases are threatening in the neighbourhood of the inflammation. The appearance is that of reddish lines on the skin, running in the long axis of the limb, or of a red blush, here or elsewhere, associated with pain, tenderness and slight œdema. Chronic lymphangitis is usually tuberculous or syphilitic in nature.

(ii) LYMPHANGIECTASIS.—This condition is usually the result of obstruction of the larger lymph vessels, causing dilatation of the smaller radicles, as by carcinoma, scar tissue, etc., or by infiltration of the walls of the vessels by tubercle or syphilis. *Elephantiasis* is a chronic affection, usually of one or both legs, leading to great increase in size of the limb. It may be congenital or acquired. In the latter case the condition may be due to infection by *Filaria sanguinis*, which causes lymph stasis and also inflammation of the skin and subcutaneous tissues.

DISEASES OF THE LYMPH NODES

A. LOCAL

(i) ACUTE LOCAL LYMPHADENITIS is generally associated with acute lymphangitis and is due to the same causes—acute septic inflammation of the skin or mucous surfaces of the part drained by the lymphatics affected. The lymphatics associated with the fauces are those most often involved, for obvious reasons. The tender and swollen nodes may suppurate, in which case the inflammation spreads, leading to peri-adenitis and involvement of the skin.

(ii) CHRONIC LOCAL LYMPHADENITIS is more often due to tuberculosis than to pyogenic infection.

CHRONIC TUBERCULOUS LYMPHADENITIS

Synonym.—Lymph Gland Tuberculosis.

This manifestation of tuberculosis, when localised, is seen chiefly in children. The cervical glands are most commonly affected, but the bronchial glands and mesenteric glands are also frequently involved.

The *cervical glands* may be invaded on one or both sides of the neck, and by their enlargement may cause much deformity. It should be remembered that frequently many more glands are diseased than can be detected by the eye or by palpation. The enlarged glands may subside spontaneously under conservative treatment, but on the other hand may become adherent and matted together. Later, caseation may ensue, the skin becomes involved and a sinus results, with discharge of sterile tuberculous pus. Secondary pyogenic infection should then be guarded against. Tuberculous glandular enlargements are always painless.

Nowadays attempts to remove masses of non-caseous tuberculous glands in the neck are rarely justified, if at all, since other infected lymph nodes must be left behind. The best treatment is general and nutritional, as advised for other forms of tuberculosis, and an open air life in a sunny coast resort is to be strongly recommended. If local caseation occurs and fluctuation is clearly detected, surgical excision must be employed, since in this way involvement of the skin, sinus formation and an ugly depressed scar may be avoided. The site of the surgical scar should be carefully chosen for its cosmetic effect, and by skilful retraction of the skin may be placed in some suitable fold away from the lesion.

The treatment of tuberculosis of the *bronchial glands* and *mesenteric glands* is discussed elsewhere.

Local tuberculous enlargement of lymph nodes in the axillæ or groins, both in children and adults, is so rare that other diseases should always be suspected.

B. GENERAL

(i) Acute Generalised Lymphadenitis. This occurs in every one of the acute infectious diseases, but is particularly frequent, and therefore of special diagnostic importance, in German measles, measles, scarlet fever and diphtheria. In glandular fever there is generalised lymphadenitis associated with mononucleosis.

(ii) Chronic Generalised Lymphadenitis. This is seen in the secondary stage of syphilis, and rarely in tuberculosis. In the latter infection the character of the nodal enlargements varies with the histological reaction to the bacillus and with the tendency to caseation, which may be well, or ill, marked. It is in cases in which caseation is delayed, or absent, that the diagnosis from lymphadenoma is sometimes very difficult, or quite impossible, in the absence of biopsy.

C. NEOPLASTIC

Lymphatic glands are invaded both by carcinoma and sarcoma. In carcinoma the involvement is secondary, and the situation and line of spread of the enlargement is often of critical importance in the diagnosis of the seat of the primary growth. Primary lympho-sarcoma is dealt with separately (p. 844), but secondary invasion by sarcoma is not infrequent.

Enlargement of lymphatic glands, local or general, in Hodgkin's disease and chronic lymphatic leukæmia, is discussed elsewhere.

HODGKIN'S DISEASE

Synonym.—Lymphadenoma.

Definition.—A disease characterised by painless, progressive enlargement of lymph nodes, usually beginning in one group and spreading to other groups, and associated with hyperplasia of lymphoid tissue in the spleen, liver and other organs, with anæmia.

The disease appears definitely to be a specific entity. Its causation is unknown. In nosology it is by some placed amongst the microbic infections, and by others amongst the neoplasmata; it has affinities with both of these processes.

Ætiological Factors.—The disease occasionally follows upon known infections—pyogenic, tuberculous or syphilitic—but in these cases it would appear to be of the nature of a secondary infection rather than an expression of any one of these diseases. It may coexist with tuberculosis. Though it may arise at almost any age, the chief incidence is during the first four decades of life. It is about twice as common in males as in females. Though sometimes seen in two or more members of the same family, there seems to be little or no real hereditary tendency.

Pathology.—The enlarged lymph nodes tend to remain discrete, and the capsule of the node is rarely, if ever, infiltrated. The masses are sometimes very large and may weigh several pounds. Individual nodes are seen to be of a pinkish-grey colour, smooth, "leathery" to the feel and, on section, show yellowish strands passing in from the capsule, with rather translucent whitish tissue between them. Areas of necrosis are unusual. Microscopic examination reveals great proliferation of the reticular endothelium, hyperplasia of the lymphoid cells and a mixture of large hyaline cells, plasma cells and eosinophil leucocytes. Some of the endothelial cells are very large and are multinuclear. These cells have some resemblance to giant cells, but their outlines are more regular and their nuclei are superposed and placed in a mass near the centre of the cell rather than ranged around the periphery. The presence of these large multinuclear endothelial cells, together with eosinophil cells, constitutes the most characteristic feature of the lymphadenomatous lesion histologically.

The *spleen* is generally enlarged at the time of death, but great enlargement, though it does sometimes occur, is unusual. The organ is quite firm, preserves its natural contours, and adhesions are often present. The surface is sometimes slightly nodular. On section the well-known "hardbake" appearance is seen—whitish-grey areas (of lymphadenomatous material) embedded in a dark red matrix (of spleen pulp).

The *liver* is the organ most often affected next to the spleen. The deposits are found to lie chiefly in the portal canals. There is usually associated fatty change.

Of other organs and tissues, the lungs, kidneys, bones and intestines are those chiefly affected.

Symptoms.—In the great majority of the cases the first symptom is the appearance of enlarged lymph nodes in the neck. The first nodes to be involved are more often in the posterior than in the anterior triangle. At this time the patient is not ill, nor does a full investigation, as a rule, discover

signs of disease elsewhere; there is little or no anæmia. Other, but less common, situations for the initial node swellings are the axillæ, the groins, the mediastinum and the abdomen. There is usually an interval of some months before general symptoms appear, and their onset is usually insidious. In some cases, however, the general symptoms advance rapidly. There is an acute type of the disease, associated with early generalisation of the node involvements, and if the original local lymph node enlargement is overlooked, the simulation of some such acute infection as miliary tuberculosis may be very close.

The features of the lymph node swellings are important. They soon become visible. They are painless, insensitive, and in the early stages of the disease they mobilise easily. To the feel, the nodes are firm and leathery. They tend to remain discrete, without involvement of the capsule and therefore without coalescence. The skin is only rarely involved; and when it is, or when, with equal rarity, the nodes undergo caseation or suppuration, this is due to secondary infection by pyogenic organisms or by tubercle. After a while the enlarged nodes tend to become massive tumours, and certain of the above features change—their mobility lessens and the individual nodes are difficult to recognise.

Two sets of symptoms now become added to the initial superficial node enlargements—the general symptoms of the disease, and symptoms referable to pressure and infiltration of the lymphadenomatous tissue in different parts of the body.

The *general symptoms* include a sense of lassitude and weakness, shortness of breath on exertion, sweating and loss of weight. Pruritus is rather common and may be very intractable. The colour of the skin changes to a *café-au-lait* tint, and in some cases a well-marked general pigmentation develops. *Pyrexia* is quite common. The form most often seen is a mild grade of remittent pyrexia, similar to that seen in tuberculosis. Not at all infrequently, however, the pyrexia assumes an undulant character, and the recognition of this type of fever is of great importance in diagnosis. It is not at all uncommonly overlooked, especially if morning and evening charts are not kept. Sometimes the undulant feature is very regular, a wave of pyrexia of some 10 to 14 days' duration is followed by an apyrexial period of somewhat shorter duration, when the pyrexial period is repeated, and so on. The symptoms wax and wane with the pyrexia, not only the general symptoms but, at times, symptoms of a focal kind. The writer has seen a case of this sort in which acute pulmonary symptoms were present, and the disease was thought to be a relapsing broncho-pneumonia. Such pyrexia as is here referred to is termed the "Pel-Ebstein type," after the two observers who first described it. There is a third, and less common, form of pyrexia: the continued type somewhat resembling typhoid fever. It occurs in severe and rapidly progressive cases.

The *anæmia*, though it may be severe, has not, despite tradition to the contrary, any special features, nor is the blood picture often helpful in diagnosis. The red blood count and the hæmoglobin estimate are those of a "secondary" anæmia. The white cells vary much in number and in kind. Leucopenia is present in some of the more acute cases, and is occasionally a striking accompaniment of the pyrexial phases in a marked Pel-Ebstein fever. In the majority of cases, however, the leucocyte count shows a

moderate rise (10,000 to 20,000). The absolute eosinophil count quite frequently lies above the top figure of the range in health (400), and this fact may therefore be of some diagnostic help.

Focal symptoms, as already stated, are due, in the main, to pressure by the lymphadenomatous masses. Mediastinal pressure causes distressing dyspnœa, cyanosis and stridor; laryngeal palsy may be bilateral and may require tracheotomy—in which case the operation may tax the resources of the most experienced surgeon. Enlarged hilum glands and invasion of the peri-bronchial tissues produce collapse of lung, pleural effusions (sometimes hæmorrhagic or chyliform), and bronchiectasis with hæmoptysis. Masses in the transverse fissure of the liver may cause jaundice and ascites.

An interesting and not very uncommon complication is a paraplegia due to meningeal involvement about the lumbo-sacral region or the cauda equina.

Diagnosis.—This is from other causes of lymphadenopathy, both local and general, such as tubercle, syphilis, the less acute form of glandular fever, leukæmia and generalised neoplasmata. There are two diseases which confuse with Hodgkin's disease in particular: these are tuberculous adenitis and lympho-sarcoma. Especially does the uncommon form of tuberculosis, termed "endothelial," cause difficulty. In such circumstances *biopsy* alone may serve to establish the diagnosis. But even then the problems may not be solved, because the node removed may not show characteristic changes, being as yet inconclusive in its early morbid appearances or being too fibrotic. Care must be exercised in the choice of the lymph node to be excised: the one most easy to remove is not necessarily the best for diagnostic purposes. M. H. Gordon has recently found that an extract of the affected lymph nodes causes an encephalitic syndrome in rabbits which he regards as specific. This biological test may therefore be used in diagnosis; its specificity requires confirmation.

Course and Prognosis.—Trousseau's description of the disease as having three stages—the stage of local lymph-node enlargement, the stage of general lymphatic enlargement, and the stage of cachexia—holds good for the great majority of cases. But cases may be acute throughout, the total duration not exceeding three months. In other instances, long periods of remission occur, and these, with modern irradiation methods of treatment, are much more frequently seen nowadays than formerly. The average duration of the disease is perhaps about five years. Patients in whom the diagnosis has been well established may be found in moderately good health ten years later. But complete arrest must be quite rare if, indeed, it occurs at all. Rather rapid "lighting up" in a quiescent case is one of the striking features of the disease, and though the condition may be, again and again, stabilised by treatment, the level of health after each active phase has passed is found to be lower than it was previously.

Treatment.—Excision of the enlarged nodes, formerly much practised, has to-day been almost completely abandoned in favour of irradiation methods, using either X-rays or radium for the purpose. Of the two methods, X-rays appear more generally useful. It is at present the usual custom to use light and frequent doses, irradiating the nodes, the spleen, the mediastinum and other parts known to be affected, mapping out the areas to be treated and selecting the angles of application with great care. These light doses may be given daily over a period of two or three weeks, and repeated after an

appropriate interval. A course of arsenic may now be administered, and nothing seems better for this purpose than the old-fashioned Fowler's solution (liq. arsenicalis) in an alkaline draught, commencing with min. 3 and gradually increasing to min. 10 or min. 15 t.d.s.p.c. General hygienic measures should be attended to throughout the treatment. Antigen therapy, based upon Gordon's researches, is on trial.

LYMPHOSARCOMA

Definition.—A disease arising in different parts of the lymphatic system, locally malignant and invading neighbouring structures; and later, spreading by the lymphatics to give rise to metastases in distant organs.

Ætiology.—The incidence of lymphosarcoma is very similar to Hodgkin's disease, but this disease is much less frequent.

Pathology.—The commonest site of origin of the disease is in the cervical lymph glands, next in the mediastinal glands, and more rarely in the tonsils, the lymphoid tissues of the naso-pharynx, the retro-peritoneal lymph glands and the lymphoid tissue of the intestine. In section the affected tissues have a homogeneous appearance. Histologically the essential diagnostic point is the uniform replacement of the normal structure of the lymph follicles by cells which are all alike and which generally closely resemble small lymphocytes. Between the cells is a fine reticulum, well shown only by special staining, and absent in ordinary "round-celled sarcoma." When the cells are uniformly larger, and possibly derived from reticulo-endothelial parts of the lymphatic system, a histological diagnosis of *endothelioma* may be justified, but otherwise the disease is identical.

Many, but not all, tumours arising in the mediastinum are examples of oat-celled carcinoma of the lung arising in a bronchus (p. 1219), so that mediastinal lymphosarcoma is less common than was formerly supposed.

In the later stages of the disease distant groups of lymphatic glands may be involved, but the spleen is not often enlarged. At necropsy secondary growths may be widespread, but are often too small to be recognised except by the microscope.

Symptoms.—When arising in the cervical lymph glands, the enlargement is rapid, matting together soon occurs, and local destruction with ulceration may ensue. Otherwise, especially if the glands involved are in deeper situations, the symptoms are chiefly those of pressure and invasion of neighbouring structures. In contradistinction to Hodgkin's disease, general symptoms are few. The patient may appear in good health, and the cachectic state seen in the late stages of lymphadenoma is absent. Fever also is much less common. The blood picture is usually not distinctive, but in a few cases may suggest lymphatic leukæmia.

Diagnosis.—This is principally from Hodgkin's disease, but other diseases of the lymphatic system should also be excluded. Removal of a suitable lymphatic gland or portion of tissue is the only rational means of diagnosis.

Course and Prognosis.—The course is more rapidly fatal than in Hodgkin's disease, but may be greatly influenced by treatment.

Treatment.—Lymphosarcoma is more susceptible to suitable X-ray treatment than almost any of the varieties of enlargement of the lymphatic

glands, and the localised masses generally disappear with great rapidity. Recurrence elsewhere, however, is soon manifest, and most patients die of asthenia. No permanent cure can yet be hoped for.

STATUS LYMPHATICUS

Synonym.—Lymphatism.

Under this term are classed, somewhat loosely, a number of cases met with in which there is hyperplasia of the lymphatic tissues in the body. The note of dramatic significance is given to these cases because, in them, sudden death is prone to occur, whether during anæsthetic administration or otherwise.

Since the thymus is found to be enlarged with great constancy in such patients, considerable importance attaches to this part of the picture, though it is probable that the essential nature of the diseased state is much more general, and that such local hyperplasia alone, though it has serious possibilities, is not responsible for more than a proportion of the fatalities.

Though the diagnosis of thymic hyperplasia is nowadays greatly assisted by X-ray examination of the thorax, by far the majority of instances of lymphatism are only discovered in the post-mortem room. Children who present a pallid and flabby facies are by no means necessarily "lymphatic" in the sense of the word here used. Nor does the presence of "thymic asthma" necessarily denote more than the local lesion of an enlarged thymus. In other words, lymphatism always presents thymic hyperplasia as one of its features, but demonstration of thymic enlargement, whether before or after death, by no means proves the existence of lymphatism. The real nature of this latter condition is quite unknown.

MIKULICZ'S DISEASE

Definition.—A slowly developing bilateral enlargement of the lachryma glands, followed by similar symmetrical enlargement of the salivary glands—the parotid, the submaxillary and the sublingual.

Ætiology.—This is unknown. The condition occurs only in adult life.

Pathology.—This disease, described in 1888, is included here rather than under conditions affecting the salivary glands because the enlargement is due to hyperplasia of the lymphoid tissues, and not of the secretory elements. Excised tissue shows changes resembling sarcoma or lymphatic leukæmia, and the condition has occasionally progressed to true leukæmia.

Symptoms.—The enlargement of the glands is symmetrical, painless and slowly progressive. The ultimate deformity may be very great. The only symptoms complained of are interference of vision and impaired salivary secretion. The general health is unimpaired.

Diagnosis.—This depends on the clinical features described. Leukæmia, Hodgkin's disease, tuberculosis and syphilis, in all of which enlargement of the salivary glands may be present, should be excluded.

Treatment.—Arsenic, potassium iodide and X-ray therapy have all been tried, but the disease pursues a very chronic course

HORDER.
J. W. MCNEE.

SECTION XIII

DISEASES OF THE CIRCULATORY SYSTEM

DISEASES OF THE HEART AND PERICARDIUM

PHYSIOLOGICAL CONSIDERATIONS

In normal circumstances it is the left ventricle which gives rise to the clinical apex-beat, and the apex-beat may then be defined as that part which is farthest to the left at which a definite forward thrust is imparted to the finger held perpendicularly to the chest. When the right ventricle is much enlarged, however, that chamber may displace the left ventricle backwards, so that the apex-beat is due to the contraction of the right, instead of the left, ventricle.

The *sino-auricular node* is a small node of specialised tissue which is situated at the junction of the superior vena cava with the right auricle. In it are nerve fibres and ganglion cells, which are connected with the vagus and sympathetic nerves. The *auriculo-ventricular node* is a small node of specialised tissue which is situated in the septal wall of the right auricle. The *auriculo-ventricular bundle*, or bundle of His, is a bundle of tissue connecting the auricles and ventricles. It arises from the auriculo-ventricular node, passes forwards in the interauricular septum, then turns downwards, and at the upper margin of the interventricular septum divides into two main branches, one of which goes to the right and the other to the left ventricle, each eventually terminating in widespread subendothelial arborizations—the Purkinje fibres. Nerve-fibres and ganglion cells are present in the auriculo-ventricular bundle, and its blood supply is mainly derived from a special branch of the right coronary artery.

The heart muscle possesses certain inherent properties, namely: Rhythmicity, by which is meant the power of generating impulses which can excite it to contract rhythmically; excitability, the power to receive impulses for contraction; contractility, that of contracting in response to impulses or stimuli; conductivity, that of conveying waves of excitation or impulses from fibre to fibre; and tonus or tonicity, a condition of sustained partial contraction, independent of systolic contractions, by virtue of which the muscle fibres offer more resistance to stretching during diastole than they would owing to their inherent elasticity or other properties alone.

The function of rhythmicity is more developed in the remains of the primitive cardiac tube than in the auricular or ventricular tissue, especially in the remains of the sinus venosus. Impulses therefore normally arise at the latter site, and there is reason to believe that they begin in the sino-auricular node, for which reason the node has been called the " pace-maker "

of the heart; the rhythm of the sinus governs that of the remaining segments of the organ. The function of conductivity is most developed in the auriculo-ventricular node, the bundle, and its branches; and that of contractility in the muscle fibres of the auricles and ventricles.

From the sino-auricular node, the wave of excitation travels to the other portions of the heart by means of the function of conductivity. It first spreads over the auricles, and auricular systole takes place. It is then conveyed through the auriculo-ventricular node, along the auriculo-ventricular bundle, its branches and ultimately the subendothelial arborizations, and is so distributed to the ventricles, the latter contracting in response to excitation waves received from the auricles.

The interval separating the commencement of auricular and ventricular contraction is of great clinical importance, for it is an index of the time-relations of the contraction of the auricles and ventricles, and of the function of conductivity of the auriculo-ventricular node and bundle above its division. It is called the *As–Vs* interval. The function of the conductivity of the heart may be measured by means of the electro-cardiograph and the clinical polygraph.

But while normally the function of rhythmicity is most developed at the sinus part of the auricle it may be so in any other portion of the remains of the primitive cardiac tube, in which event the impulses are generated at that particular point; for this reason the different parts of the heart are capable of starting independent contractions. They may arise in the auricle; or in the auriculo-ventricular node or the bundle above its division; or in the ventricle itself, probably in the subendothelial arborizations.

When the impulses are generated in the sinus part of the auricle, we speak of normal or sinus rhythm. When they arise at an abnormal point, *i.e.* at some site other than the sinus, the abnormal focus is sometimes termed *ectopic* (Lewis) or heterotopic (Hering), and the contraction an *ectopic* beat. The term *ectopic* rhythm also is sometimes employed.

When the ventricular contraction is the result of an excitation wave which comes from above the division of the auriculo-ventricular bundle, it is sometimes termed supra-ventricular in origin; and when it is due to an impulse generated below the division of the bundle, it is sometimes called of ventricular origin.

When the ventricular contraction is supra-ventricular in origin, but the manner of conduction of the wave of excitation along the normal channels is abnormal, the ventricular beat is sometimes called *aberrant*.

In what is termed *auriculo-ventricular nodal rhythm*, the impulses arise in the auriculo-ventricular node, and travels upwards into the auricles and downwards into the ventricles, giving rise to a simultaneous contraction of both auricles and ventricles.

When the ventricles beat independently of the auricles, the independent rhythm of the ventricles is called "idio-ventricular" rhythm. It is found only in association with auriculo-ventricular block.

Throughout systole the heart muscle is absolutely refractory and so does not respond to a stimulus, whatever its strength. Immediately after systole the muscle is relatively refractory, during which it may respond to a stronger stimulus but not to a weaker one. When stimulated, the cardiac muscle either does not contract at all, or it does so to the fullest possible extent at the

time, whether the stimulus be weak or strong; it is a case of "all or none." The longer the time that has elapsed since the previous contraction, the weaker is the stimulus required to bring about a further contraction. Further, the greater the degree of excitability of the muscle-fibres, the weaker is the stimulus required, and the earlier in the refractory period will the heart contract. The amount of contraction does not depend upon the strength of the stimulus employed, but varies according to the time at which the stimuli are applied. When a contraction occurs early in diastole, the contraction in the succeeding cardiac cycle is weaker than that preceding it. Within certain limits, the degree of contractility depends upon the length of the preceding diastole; the greater the period of rest, the more perfect and full is the recovery. It can, therefore, be readily understood that the greater the heart-rate the greater is the possibility of cardiac failure. Similar laws apply to each of the other special functions of the heart muscle. In the case of conductivity, for example; when conduction occurs, this function has been exercised to the fullest extent possible at the time of stimulation. The refractory period follows immediately after the conduction of a stimulus, and during this brief period the muscle-fibres cannot again conduct a stimulus, conductivity being completely exhausted. Restoration, however, quickly commences, and ultimately the function is restored. The extent of the relaxation between the contractions depends upon the degree of tone present, and upon the rate of the heart-beat. With a slower rate there is, of course, more time for full relaxation. There should be a sufficient period of rest after each function has been exercised. Within certain limits, the greater the period of rest the more perfect and full is the recovery of each special function. In heart failure one or more of the five fundamental functions of the fibres of the heart muscles are at fault, and, if this occur to two or more simultaneously, the different functions are not necessarily equally affected. From what has been said, the value of rest in heart failure can be readily understood.

The pulsus alternans is probably an indication of depressed contractility of the heart. When conductivity of the heart is impaired, there is some degree of heart-block. A lowered state of tonicity results in dilatation of the heart and it may be of the auriculo-ventricular orifices.

The heart has the power of rhythmically contracting and dilating, due to an inherent power possessed by the cardiac musculature, independent of any extrinsic nervous influence. Nevertheless, the activity of the various functions of the muscle-fibres is under nervous control. Both the inhibitory fibres of the vagus and the accelerator fibres of the sympathetic are normally in a state of tonic activity, and the cardiac centres are in a state of continuous slight excitation.

The Cardiac Cycle.—Stated briefly, in the cardiac cycle there occur in rapid succession auricular systole, ventricular systole and ventricular diastole. There are three phases in the systole of the ventricles, namely: (*a*) The period during which all four valves are closed; this is called the pre-sphygmic period. (*b*) The period during which the semilunar valves are open; this is called the sphygmic or pulse-period. (*c*) The period between the closure of the semilunar valves and the opening of the auriculo-ventricular valves; this is called the post-sphygmic period. It should be noted that the sphygmic or pulse-period in a tracing of the cardiac apex, carotid pulse or radial pulse, does not refer to the actual time of occurrence of ventricular systole, but

to a period in the tracing; and, on account of the distance from the heart, the sphygmic or pulse-period will necessarily be later in a radial tracing than the same period in a tracing taken at the cardiac apex or over the carotid. The periods of time which elapse between the apex-beat and the carotid pulse, and between the carotid and radial pulses, have each been found to be $\frac{1}{10}$th of a second; the pulse-period, therefore, in a radial tracing commences about $\frac{1}{10}$th of a second behind the same period in a tracing of the carotid, and about $\frac{1}{5}$th of a second behind that in a cardiogram.

Assuming that in normal health the human heart beats about 72 times per minute, each cardiac cycle, therefore, is completed in about $\frac{8}{10}$ths of a second, this time being divided up in the following manner: systole of auricle, $\frac{1}{10}$th of a second; systole of ventricle, $\frac{3}{10}$ths of a second; diastole, $\frac{4}{10}$ths of a second. The most stable part of the cardiac cycle is the ventricular systole, and the most variable is the diastole. The rate of the heart-beat mainly depends upon the duration of the diastole. When the heart beats unusually quickly, the duration of the diastole is shortened by a greater degree than that of the systole; in other words, when the period of the cardiac cycle decreases it is the long pause which is particularly shortened.

THE CLINICAL POLYGRAPH

The clinical polygraph was the instrument employed by Mackenzie in his epoch-making researches on irregular action of the heart and the results of the administration of the digitalis group of drugs in those suffering from cardiac affections.

By means of this instrument the movements of both auricles and ventricles can be recorded graphically, the time-relations of the contractions studied, and the function of conductivity of the auriculo-ventricular bundle above its division measured. It is possible to identify sinus arrhythmia, the various types of extrasystoles, the various degrees of auriculo-ventricular heart-block, the pulsus alternans, auricular fibrillation, and a proportion of cases of auricular flutter. At the present time, however, the clinical polygraph has largely been superseded by the electrocardiograph in clinical practice, since the latter gives practically all the information to be obtained by the polygraph, its findings are more accurate, and it provides additional information (see p. 999.)

Clinical electrocardiography is dealt with at the end of the Section.

By means of the clinical polygraph it is possible to obtain tracings of any two of the following: The radial or brachial pulse, the apex-beat, the carotid pulse, the jugular pulse, the liver pulsation, and the respiratory movements. A time-marker registers $\frac{1}{5}$th of a second on the recording surface. For clinical purposes, it is usual to take simultaneous records of the radial or brachial pulse, and of the pulsation of the jugular vein at the root of the neck. A tracing of the radial pulse is called a sphygmogram or arteriogram, and a tracing of the venous pulse is called a phlebogram.

THE PHLEBOGRAM.—In a normal phlebogram, in each cardiac cycle, three main elevations, separated by three depressions, are to be observed (Fig. 20). The three waves are called the *a*, *c* and *v* waves respectively. The *a* wave is due to the auricular systole. The *c* wave is probably due to the impulse

of the carotid artery, but a similar wave occurs in intra-auricular pressure curves and, therefore, the *c* wave may be partly venous. The *v* wave is due to stasis; during ventricular systole the pressure in the right auricle and jugular vein rises steadily, falling suddenly with the opening of the auriculo-ventricular valves, and this sudden fall of pressure marks the summit of the *v* wave. Occasionally a fourth wave, the *h* or *b* wave, occurs in diastole

FIG. 20.—Simultaneous tracings of the jugular and radial pulses, showing the normal form of venous pulse. Note that the *a*–*c* interval is $\frac{1}{5}$th second, and that the summit of the *v* wave coincides with the dicrotic notch of the radial pulse.

between the *v* wave and the *a* wave of the next cycle (Fig. 21). The waves of the jugular curve are identified by their time-relations to points on the radial pulse. The commencement of the *c* wave occurs $\frac{1}{10}$th second before the main radial upstroke, and the summit of the *v* wave is synchronous with the bottom of the aortic notch in the radial pulse. When the *v* wave is double (v^1 and v^2), the apex of the second *v* wave is synchronous with the aortic notch. The *a* waves are recognised by exclusion, after identifying the *c* and *v* waves. The period of ventricular systole corresponds in time to the segment of the venous curve between the commencement of *c* to

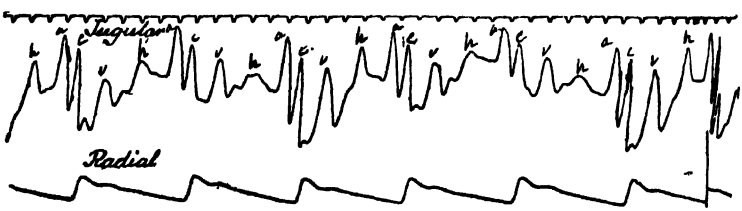

FIG. 21.—Simultaneous tracings of the jugular and radial pulses. The jugular curve shows the *h* or *b* wave.

the summit of *v*. The *a*–*c* interval, from the commencement of the *a* wave to the commencement of the *c* wave, approximately represents the conduction time between auricles and ventricles, and measures normally between 0·15 and 0·2 seconds. If it exceeds $\frac{1}{5}$th second, it indicates depressed conductivity by the auriculo-ventricular node or bundle. When the cardiac rate is unusually frequent, the duration of the diastolic

interval is shortened, so that the *v* wave approaches more and more to the following *a* wave, and *v* and *a* may even coincide and superimpose.

In cases of great distension of the right auricle the *c* and *v* waves coalesce to form a plateau-shaped wave (Fig. 22). This was described by Mackenzie

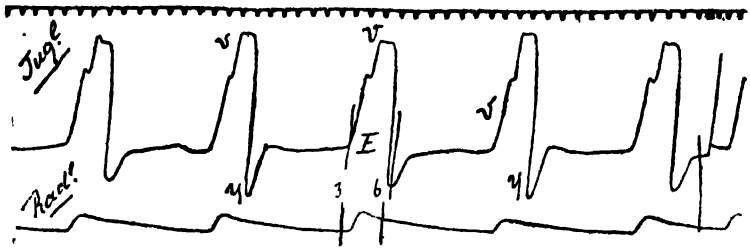

FIG. 22.—Simultaneous tracings of the jugular and radial pulses, from a case of auricular fibrillation, showing the ventricular form of venous pulse, and an unusually slow radial pulse.

as the ventricular form of venous pulse when it occurred in the absence of the *a* waves, but the condition is due to the great distension rather than to auricular fibrillation.

CIRCULATORY FAILURE

It is necessary to point out that there are two varieties of circulatory failure, namely, cardiac or central, and peripheral. In the first variety the fault lies in the heart itself. In the second, there is failure of the circulation at the periphery. In some cases both forms are present, as may occur in diphtheria and pneumonia.

It is important to note that syncope may be cardiac, or peripheral, in origin, and is much more commonly due to the latter.

A. HEART FAILURE

In the study of heart disease it is of fundamental importance that we should have a true conception of the principles which underlie heart failure. It is also of much practical consequence to recognise the beginning of failure, and, in addition, to distinguish between the various degrees which may arise later.

It should be understood that the essential cause of cardiac failure lies in the heart muscle, and is due to changes in the heart muscle which render it unable to maintain an efficient circulation. If this view of the causation of heart failure be correct, valvular defects and disturbances of the cardiac mechanism, such as auricular fibrillation, and diseased conditions of the blood vessels, should be regarded from the point of view of the relation which they bear to the myocardium, as well as specific affections in themselves. Let us take the case of a valvular lesion: First of all, it can be readily understood that it is a mechanical impediment to the heart muscle in its work. But it should be remembered that there are, as a rule, along with the chronic valvular lesion, coincident changes in the cardiac musculature, or the blood

vessels, or both. In all cases of chronic valvular disease, therefore, it is of importance that we should endeavour to ascertain whether the lesion which has invaded the valve has also affected the myocardium, or the blood vessels, or both, and, if so, to what degree.

By the 'reserve force' of the heart is meant the force inherent in the cardiac muscle which is called upon when bodily effort is made; and by the 'rest force' is meant the force inherent in the muscle of maintaining an efficient circulation when the body is at rest.

The reserve force may be estimated by the response of the heart to effort. This includes: (1) The effect of a standard piece of physical exertion on the cardiac and respiratory rates, which is called the 'exercise tolerance test. The pulse rate should not be unduly increased, and it should return to its former level within two minutes after the cessation of the effort. (2) That which is of much greater value, the amount of physical exertion in which the patient can indulge without experiencing abnormal subjective symptoms.

In our investigation of the reserve force of the heart, it is necessary to emphasize the following. The natural standard of the cardiac strength varies in different individuals, each knowing the amount of exertion in which he can normally engage without producing subjective symptoms. Our inquiry should aim at finding out whether there has been a departure from such, and, if so, in what degree. Again, a departure from the normal standard may be due to temporary or extraneous causes, such as deficient tone the result of lack of physical exertion, fatigue, upward displacement of the contents of the abdominal cavity, anæmia, and broncho-pulmonary morbid affections.

Inquiry should also be made whether any departure from the normal standard is increasing, and, if so, whether in spite of an adequate period of rest and the employment of other remedial measures.

By heart failure is meant the condition in which the cardiac muscle is unable to maintain an efficient circulation. It almost invariably begins with a diminution of the reserve force of the heart. This manifests itself by a limitation of the area of cardiac response, *i.e.* an individual cannot indulge in physical exertion which formerly he was able to do without experiencing subjective symptoms. These may appear as the result of less and less effort, until ultimately the 'rest force' is diminished, some or all of the symptoms being present even during rest, and objective signs also become evident.

It may be mentioned here that while the terms 'compensation' and 'decompensation' or failure of compensation sometimes used with reference to chronic valvular disease (see p. 927) are not strictly synonymous with the absence and presence of cardiac failure respectively, for practical purposes they correspond with them.

The onset of heart failure may be gradual, or more or less rapid or even abrupt, usually the former. Among the most common symptoms are difficulty in breathing (dyspnœa), fatigue, palpitation, discomfort or pain, giddiness, and faintness or actual syncope, referred to exertion. I would again emphasize that these may also be the result of temporary or extrinsic causes, some of which have been mentioned.

Difficulty in breathing is the most frequent and earliest symptom, and is more frequent in mitral than in aortic disease. Its degree may be so slight that the patient himself may only observe it on over-exertion. Later, however, the dyspnœa may be induced by less and less effort, until ultimately

it may be brought on by such slight forms as walking slowly on the level, or on changing the position in bed; it may, indeed, be present without any effort. The degree may amount to orthopnœa, that is, the patient may be unable to lie down.

There may be paroxysms of dyspnœa, or what is termed cardiac asthma. In the great majority of cases they occur during the night, and perhaps especially when the patient is falling off to sleep, but very occasionally, especially in mitral stenosis, on over-exertion during the day. The attack comes on suddenly, with a sense of suffocation, the intensity of which may be extreme and compel the patient to breathe in a laboured manner and, if in bed, to sit up. There may be a sense of oppression in the chest, cough, frothy expectoration, which may be blood-stained, wheezing, sweating, and cyanosis. Rhonchi and bubbling râles may be audible, and the second sound in the pulmonary area may be accentuated. After a time, lasting from a few minutes to a few hours, the attack subsides. If due to left ventricular failure, not infrequently there is gallop rhythm, presystolic in time (see p. 856), and less often pulsus alternans, especially in hypertension. Acute pulmonary œdema may occur.

Paroxysmal dyspnœa and acute pulmonary œdema are believed to be due to paroxysmal venous congestion and paroxysmal pulmonary œdema respectively, the result of disproportionate activity between the two sides of the heart. They occur especially in hypertension, aortic incompetence or stenosis, chronic myocardial disease, and atheroma of the coronary arteries, with more or less sudden failure of the left ventricle. They may rarely be met with in marked mitral stenosis with sudden tachycardia, with increased output by the right ventricle, but apparently not if there is gross dilatation of the left auricle or auricular fibrillation. In both groups of cases there is disproportionate activity on the part of the two sides of the heart. Paroxysmal dyspnœa and acute pulmonary œdema are generally relieved if right-sided failure or auricular fibrillation supervenes, and usually recur if these are successfully treated.

Cheyne-Stokes respiration sometimes occurs, and is usually the result of chronic heart disease, especially in left ventricular failure. At first, it is generally during sleep and is slight, consisting merely of waxing and waning of respiration, but later, there may be actual apnœa and hyperapnœa. If during the day, it is of more serious significance.

Fatigue, usually related to physical or mental effort, generally the former, is not an uncommon symptom of cardiac failure. While palpitation may be due to such (see p. 876), it is much more frequently met with apart from it. Discomfort or pain is a relatively infrequent manifestation of heart failure. Some are of opinion that failure is never a cause of such. I do not share this view, although I would point out that even in the subjects of organic morbus cordis pain is generally due to extrinsic causes. For differential diagnosis, see p. 877. The pain of angina pectoris is described on p. 984. There may be a sensation of weight or oppression over the precordium in cardiac failure.

Symptoms due to cerebral anæmia the result of failure on the part of the heart to maintain an adequate supply of blood to the brain are not infrequent. They include early fatigue on mental effort, sleeplessness, disagreeable dreams, giddiness, faintness or actual syncope, lack of power of concentration, impairment of memory, headache, nervousness, loss of emotional control,

mental irritability, and, in severe cases, even insanity. Giddiness may be slight and transient, or severe enough to cause the patient to fall.

It is important to note that syncope may depend upon a fault in the heart itself, *i.e.* it fails to propel an adequate amount of blood into the arteries; or upon failure of the venous return to the organ, due to vaso-dilatation, especially of the splanchnic area.

The latter is much more common. In such there is a preliminary fall of blood pressure. There are two varieties, namely, that associated with posture, and what are called *vasovagal attacks*. The former is more frequent in the elderly or middle-aged. The pulse becomes feeble and may be imperceptible. Vasovagal attacks are more common in the young, and are apt to be associated with emotion, a heated stuffy atmosphere, or fatigue. They rarely occur when the patient is lying down. There is not only a preliminary fall in the blood pressure but also a diminution in the cardiac rate due to increased vasovagal tone, both of which may be marked. There is profuse sweating, respiration becomes slow and may almost cease, the face may become of a greenish pallor, there may be dilatation of the pupils, nausea and vomiting, and occasionally slight convulsions of the face and arms and trunk. Full recovery is usually slow.

Syncope of primary cardiac origin may occur in auriculo-ventricular block (see p. 908), paroxysmal tachycardia, 1 : 1 auricular flutter, and occasionally in organic morbus cordis, most commonly in aortic valvular disease and chronic myocardial disease. It should be remembered, however, that syncope in the last two may also be the result of failure of the venous return to the heart. In paroxysmal tachycardia and 1 : 1 auricular flutter, the amount of blood propelled by the heart at each systole is so small as to give rise to cerebral anæmia. There is a severe fall of blood pressure, whereas in auriculo-ventricular block there is no fall. In aortic and chronic myocardial disease syncope is usually associated with physical exertion.

There may be cough, generally with expectoration, which may be only nocturnal, and slight wheezing. Hæmoptysis is not infrequent, and may be the result of venous congestion or of a pulmonary infarct. Cough and hæmoptysis are most common in left ventricular failure and mitral stenosis. Cardiac asthma and acute pulmonary œdema have been dealt with. There may be physical signs of venous congestion and œdema of the lungs, which may be limited to the bases, or more or less widespread; and, later, of hypostatic pneumonia. The vital capacity of the lungs is diminished, and the pulmonary circulatory rate is decreased. Radiological examination may reveal evidence of pulmonary congestion or œdema. There may be hydrothorax, the result of pulmonary congestion, in which event it is generally left-sided. The pulmonary artery and its branches may become dilated and even atheromatous. There is a tendency to affections of the respiratory system, such as bronchitis and broncho-pneumonia, in heart disease, especially with mitral stenosis.

Digestive symptoms are common, being due either to venous congestion or to deficient blood supply of the alimentary organs, more commonly the former. They may take the form of loss of appetite, gastro- and intestinal flatulence, a sense of fulness, pain in the epigastrium and between the shoulder blades, nausea or vomiting, constipation, or, rarely, diarrhœa. When venous engorgement has become established, the liver may be palpable,

having a sharp edge and smooth surface, and may be tender and rarely pulsating. In severe hepatic congestion there may be a continuous aching pain, sometimes accompanied by rigidity, in the right hypochondrium. Jaundice is infrequent. Ascites may develop.

There may be visible distension and it may be also pulsation of the jugular veins. Cyanosis may be an indication of cardiac failure, especially in congenital morbus cordis and mitral stenosis, being less frequent in aortic disease. There may be lividity of the lips, the cheeks, tips of the ears, and finger nails, while clubbing of the fingers may be present in chronic cases. There may be polycythæmia. It is to be noted that the degree of cyanosis due to heart failure is not a reliable indication of the degree of the latter.

It is important to exclude other causes of cyanosis, such as broncho-pulmonary affections, methæmoglobinæmia, sulphæmoglobinæmia, and cases of a venous-arterial shunt in which at least a third of the venous blood passes directly into the systemic circulation, such as may occur in patent interventricular septum, patent interauricular septum, and patent ductus arteriosus. In these conditions the cyanosis arises in a different manner than when the result of cardiac failure, and there is little or no dyspnœa and an absence of other indications of failure. At the same time it is to be remembered that in the cases of a venous-arterial shunt mentioned, cyanosis due to cardiac failure may supervene.

Œdema is an important and usually a late manifestation of cardiac failure. It is more likely to occur in mitral and chronic myocardial than in aortic lesions, and in the last named tends to supervene much later and to be of much more serious significance than in the case of mitral disease. It is to be noted that generally there is an increase in a patient's weight for some time before pitting can be detected, and a loss of weight for some time after its disappearance. Œdema of cardiac origin almost always commences in the most dependant parts of the body, and in the evenings. In those who are up and about some puffiness round the ankles is first evident. The œdema increases and extends upwards, and may involve the thighs, the genitalia, the trunk, and towards the final stages may become general, but even in severe and prolonged cases occasionally it is limited to the lower extremities. If the patient is confined to bed, the sacral region, the back of the thighs, the back of the malleoli and, it may be, the genitalia are first involved. The serous membranes may be implicated, with resultant hydrothorax, ascites, and occasionally hydropericardium. Hydrothorax may be due to pulmonary or to systemic venous congestion or both. In the first it is usually left-sided, and in the second generally right-sided. Very occasionally, mostly confined to constrictive pericarditis and mitral stenosis, œdema commences in the abdomen and may even be limited to this.

Œdema indicative of cardiac failure may be recognised by the fact that it almost always commences in the most dependent parts, and that there is an increase in the general venous pressure. Hydrostatic œdema is also not uncommon in heavy people, especially of middle age and later, particularly in those who stand or sit much and with little or no movement of the lower extremities, and most often in hot weather. It sometimes occurs in varicose veins, severe anæmia, some nutritional disorders, as a terminal event in great wasting, and in local obstruction of the venous circulation, for example, by pressure from without, as in tumour, or venous thrombosis. In the differential

diagnosis of cardiac œdema, renal œdema, beriberi, myxœdema, and Milroy's disease should be considered. Œdema of renal origin usually commences in the face and in the mornings.

The urine may be scanty, high-coloured, of high specific gravity, exhibit an excess of urates, and may contain albumin or even blood.

Loss of flesh may be present, and when heart disease occurs in the early years of life, development may be arrested. Embolism, as well as arterial and venous thrombosis, may be an expression of cardiac failure.

There is usually tachycardia, but very occasionally bradycardia is to be noted. The volume and force of the pulse are often diminished. The apex-beat may be displaced, chiefly outwards. It is diffuse and weaker or occasionally tapping in character. The area of cardiac impairment is increased transversely, being more so to the left when the left ventricle is chiefly involved, and *vice versa*. The first sound is frequently diminished, and may also become short, sharp and clear, and resemble a second sound. The long pause is sometimes diminished. If there is tachycardia, there may be tic-tac rhythm. There may be a systolic murmur in the mitral or tricuspid area, due to relative incompetency of either of the valves. The arterial blood pressure varies in cardiac failure. It may fall, in which event the diastolic tends to diminish relatively less than the systolic, as is usually the case in left ventricular failure; or it may rise; or it may rise until shortly before death.

Not infrequently there is gallop rhythm, presystolic in time, or, more rarely, pulsus alternans, especially in hypertension. The former is best audible at the apex or between it and the xiphisternum. There are three distinct heart sounds. The third is related to the first sound of the next cardiac cycle, and the intervals between the three sounds are about or quite equal. There is usually reduplication of the apex-thrust. Not infrequently there is associated bundle-branch block or arborization block. Gallop rhythm, presystolic in time, cannot exist with auricular fibrillation. The prognosis in gallop rhythm is in the great majority of cases very serious.

It may be advisable to mention here that there are other varieties of triple rhythm, *i.e.* three actual sounds, at the apex: (1) The result of the third normal sound of the heart. (2) An early diastolic murmur, quickly following the second sound, in mitral stenosis may resemble a third sound, and a reduplication of the second sound and a triple rhythm are simulated. The murmur is separate but quickly follows the second sound, and is short. There is usually auricular fibrillation. (3) A reduplication of the first sound in the first grade of auriculo-ventricular block in which the interval between the contraction of the auricles and ventricles is unusually long. (4) A reduplication of the second sound may also simulate a triple rhythm. This, however, is easily recognised in that it is most evident at the base.

Lastly, sudden death, in the vast majority of cases due either to ventricular fibrillation or to sudden standstill of the ventricles, may occur, even without previous manifestations of heart failure.

The type of cardiac failure associated with chronic venous congestion, either pulmonary, or portal, or peripheral, or two or three together, is often described as *congestive failure*. There are three main clinical types of heart failure, namely: (1) the congestive; (2) that associated with systemic anæmia; and (3) angina pectoris.

Cardiac failure may be left-sided, or right-sided, or both, in which event one side may be affected more than the other. Left-sided failure is much more common than right. The latter is apt to supervene sooner or later. Left-sided failure occurs most frequently in hypertension, aortic valvular disease, atheroma of the coronary arteries, and chronic myocardial disease. Right-sided failure may be primary, among the causes being chronic mitral disease, especially stenosis, pulmonary stenosis, and broncho-pulmonary conditions; or secondary to left-sided failure.

In left-sided failure, there may be symptoms of systemic anæmia. The chief manifestations, however, are pulmonary. These have already been described in detail. They include cough, which may be nocturnal, pulmonary congestion or œdema, confined to the bases or more or less widespread, orthopnœa, cardiac asthma, and acute pulmonary œdema. The vital capacity of the lungs and the pulmonary circulation rate are diminished. If there is hydrothorax, it is usually left-sided. In addition, there may be gallop rhythm, presystolic in time, or pulsus alternans. The rhythm is usually normal, but extra-systoles, or very occasionally auricular fibrillation, may be present. Unless there is also right-sided failure, the venous pressure is not increased.

In right-sided failure, there are manifestations of venous congestion, either peripheral, or portal, or both. These have already been dealt with. They include œdema, diminished output of urine, distension of the jugular veins, enlargement of the liver, and cyanosis. The venous pressure is increased. If there is hydrothorax, it is generally right-sided.

In our inquiry regarding cardiac failure, it is not enough to ascertain whether the patient experiences any cardiac symptoms on physical exertion which formerly he was able to do, and how easily such are induced. The presence and the degree of failure as evidenced by objective signs should also be investigated.

It may be helpful to indicate what, in my opinion, speaking broadly, may be regarded as clinical manifestations of four degrees of cardiac failure, namely: 'slight,' 'moderate,' 'severe,' and 'very severe or extreme.'

Slight.—Shortness of breath, palpitation, fatigue and, it may be, præcordial pain on exertion which the patient formerly could do without experiencing this.

Moderate.—Shortness of breath and palpitation on moderate exertion, such as walking at the ordinary rate on the level; slight œdema of the lower extremities; chronic venous congestion and œdema of the bases of the lungs; slight enlargement of the liver; increased rapidity of the pulse-rate while at rest.

Severe.—Shortness of breath and palpitation on slight exertion, such as walking slowly on the level, or on changing position in bed; a considerable degree of œdema of the lower extremities in mitral cases and a moderate degree in uncomplicated aortic cases; diffuse chronic venous congestion and œdema of the lungs; a considerable degree of enlargement of the liver; orthopnœa; cardiac asthma; slight acute pulmonary œdema; œdema of the serous membranes; tic-tac rhythm; gallop rhythm, presystolic in time.

Very Severe or Extreme.—Pronounced continuous shortness of breath; severe dyspnœa on walking slowly on the level, or on changing position in bed; general anasarca in mitral cases and a considerable amount of œdema

of the lower extremities in uncomplicated aortic cases; marked enlargement of the liver; severe acute pulmonary œdema; persistent pulsus alternans in the absence of a marked acceleration of the cardiac rate.

The degree of cyanosis *per se* is not a reliable indication of the degree of cardiac failure, since it largely depends upon the variety of the cardiac affection.

It might be contended that the fact that an individual cannot engage in physical exertion which formerly he was able to do without experiencing cardiac symptoms does not signify cardiac failure. I would reply that, subject to the conditions mentioned, it does, although the failure may be of slight degree. I would repeat, however, that a departure from the normal standard of an individual may be due to extrinsic or temporary causes.

It is to be observed that the same amount of right-sided failure in uncomplicated aortic cases signifies a more severe grade of failure than in mitral cases.

Having discussed the manifestations and varieties and degrees of cardiac failure somewhat fully, much repetition will be saved in describing the clinical features of the various cardiac affections.

In conclusion, it may be advisable to make a few remarks regarding the pathogenesis of heart failure.

In the early part of the nineteenth century, Hope put forward what is called the back-pressure theory. By this is meant that the chronic venous congestion in chronic valvular affections takes place behind a failing ventricle. This view was generally adopted. Later, it was qualified and amplified by Stokes, who laid stress upon the myocardial factor. In the early part of the present century, a fundamental change took place, *i.e.* what is termed the forward-pressure theory was proposed and generally accepted, notably by Mackenzie. By this is meant that the venous congestion occurs in front of a failing ventricle, the output of which is diminished, with consequent deficient supply of blood to the various organs and an increased amount in the venous circulation. According to the back-pressure theory chronic venous congestion in the systemic circulation is indicative of left-sided failure and venous congestion of the pulmonary circulation signifies right-sided failure; and in the forward-pressure theory chronic venous congestion in the systemic circulation is indicative of right-sided failure and venous congestion of the pulmonary circulation signifies left-sided failure.

Recent clinical, radiological, and experimental evidence, including on the chemistry of the blood, together with post-mortem findings strongly suggest that the forward-pressure theory does not fully explain the phenomena of cardiac failure. It is probable that in cardiac failure both deficiency in output and back-pressure are involved.

B. Peripheral Circulatory Failure

Syncope due to peripheral circulatory failure has already been referred to.

Acute peripheral circulatory failure may occur in the toxæmia of some acute infective diseases, such as diphtheria and acute pneumonia; in traumatic shock after severe injuries; and in post-operative collapse. The blood accumulates in the capillaries, with consequent failure of the venous return of blood to the heart. The veins are depleted.

There is weakness, faintness, it may be restlessness, a small rapid pulse,

a severe fall of both systolic and diastolic blood pressure, rapid and shallow respiration, pallor, cyanosis, and coldness of the body-surface.

Unlike cardiac failure, there is an absence of chronic venous congestion.

PROGNOSIS IN CARDIAC AFFECTIONS

Prognosis in cardiac affections is a subject of considerable importance, and often presents great difficulties. From the nature of the ailment, the reasons for the former are not far to seek. Among these are the fact that the patient and his friends are naturally anxious for an opinion as to the probable duration of life, the ability of the patient to lead within limits a fairly normal existence, and perhaps also his capacity for employment.

In trying to form a prognosis in any given case of cardiac disorder, the following points require consideration: the family history; the age, the sex, the occupation, the mode of life, and the social conditions of the patient; the age-incidence of the cardiac affection; the health of the patient subsequent to the commencement of the cardiac affection; the cardiac affection—its ætiology, its variety, its degree, its duration, and whether it is stationary or progressive; the integrity of the myocardium; the question of cardiac failure; the risk of sudden death; the general health of the patient, and the existence or otherwise of complications; and the response of the patient to treatment.

With regard to the family history, we should note whether any other members of the family have suffered from any form of cardio-vascular disease, and the average period of longevity. The younger the patient the more likely is the cardiac affection to be the result of antecedent acute inflammation, and at or after middle life to a primary chronic affection. In the case of both, after adult age the cardiac reserve is more likely to be less as age advances. Taking all cases of cardiac affections into account, the prognosis is better in females than in males. The former are less subject to physical and mental strain, in them mitral disease is relatively more common than aortic disease, and chronic myocardial disease and arterial disease are relatively of less frequent occurrence. On the other hand, in females mitral stenosis is much more frequent, the strain at puberty is greater, and the risks of pregnancy and parturition have to be considered. Any occupation or mode of life involving undue physical or mental strain or exposure, unhealthy habits, such as over-eating or over-drinking, and unfavourable social conditions cause the outlook to be less favourable.

The younger the age-incidence, the less favourable the prognosis. Among the reasons for this are that: (1) in early life the heart is less able to undergo compensatory changes during the period of active growth, and any form of cardiac affection has a deleterious effect upon the general physique and mental development; (2) in early life rheumatic endocarditis is more likely to be accompanied by myocarditis and pericarditis; and (3) there is a greater liability to the recurrence of the cause of the cardiac affection, with possible increased damage to the heart. If the cardiac affection has existed for a considerable time and the health of the patient is still good, the outlook is correspondingly hopeful; and the converse is the case.

Taking cases as a whole, when a chronic valvular affection is the result of

a previous attack of acute endocarditis, the prognosis is not so serious as when due to a primary chronic degenerative process, because in the latter the lesion is apt to come on after middle life, to be progressive, and to be associated with chronic myocardial disease. It should be remembered, however, that in the case of the former, the patient is liable to recurrent attacks and consequent further crippling of the valve. If a lesion is due to syphilis, taking cases as a whole, the prognosis is very unfavourable.

With regard to the variety of the cardiac affection, the prognosis of aortic is less favourable than that of mitral disease, and lesions affecting both valves graver than when one only is involved. It is difficult to give the order of relative gravity of lesions affecting the different valves, but so far as four varieties of chronic valvular disease are concerned, most writers place in order of gravity, aortic incompetence, mitral stenosis, aortic stenosis and mitral regurgitation. With regard to aortic stenosis, however, a qualification is necessary; it refers only to those cases which are due to antecedent acute endocarditis. Among the points which may be of assistance in trying to estimate the degree of the cardiac affection are the degree of modification of the character of the pulse, of the blood pressure, of the cardiac sounds and cycle, the size of the heart, the time of occurrence, the duration, the character, and the area of propagation of any existing murmur or murmurs, and the degree of any existing auriculo-ventricular block. As examples, in chronic valvular disease: in mitral and tricuspid stenosis, the duration of a presystolic murmur and whether there is also a diastolic murmur, and, if so, its length; and in mitral incompetence and aortic incompetence, whether a murmur merely accompanies or replaces the cardiac sound, its length, and its area of propagation.

When the cardiac affection is the result of a previous attack of an acute inflammation, generally speaking, the shorter its duration the less favourable the prognosis, because (1) there is less chance that the inflammatory process has become quiescent; (2) it is less possible, especially in mitral stenosis, to estimate whether the fibrous cicatricial tissue resulting from the acute inflammatory process has ceased to contract; and (3) the patient is more liable to recurrent attacks of the cause, such as acute rheumatism, with possible consequent further damage. In endeavouring to arrive at a decision whether the cardiac affection is stationary or progressive, the following points should be considered: whether the standard of the response of the heart to effort is diminishing; the question of cardiac failure; whether there is an increase in the degree of modification of the character of the pulse, of the blood pressure, and of the cardiac sounds and cycle; the size of the heart; whether there is an alteration in any existing murmur or murmurs—such as whether a murmur replaces instead of accompanies the cardiac sound, or an increase in the length of an apical presystolic, or the supervention and the length of an apical diastolic murmur; and is there an increase in any existing auriculo-ventricular block?

In chronic valvular disease the integrity of the myocardium is of fundamental importance. Is it involved or not, and, if so, to what degree? In this connection the response of the heart to effort and the question of cardiac failure are of value, and are discussed elsewhere. When the degree of limitation of the response of the heart to effort, and, if present, the degree of other manifestations of failure are in excess of what might be expected considering

the variety and degree of the valvular affection, provided a cause for such can be excluded, the greater likelihood, and the more severe the degree, of myocardial involvement. In addition, the size of the heart, to what extent the cardiac sounds and cycle are modified, the cardiac rhythm, including whether there is auriculo-ventricular block, and, if so, of what degree, whether there is bundle-branch block, arborization or intraventricular block, or some other form of disordered action of the heart, are of moment.

The question of cardiac failure is also of cardinal importance. Whenever cardiac failure is present, two points should be taken into consideration, namely, its degree and the circumstances of its onset. The clinical manifestations of the various degrees of cardiac failure are described on pp. 857, 858. With regard to the second point, inquiry should be made as to whether the failure is due to a cause which might reasonably be expected to account for it, and is either temporary and not likely to recur, or persistent but remediable, or is not.

With reference to the risk of sudden death in cardiac affections, the commonest lesions are those of the coronary arteries themselves or involvement of their orifices (see p. 948). Such an event may be due to coronary occlusion, or independent of it. Sudden death is not uncommon in cases of angina pectoris, and may be due to ventricular fibrillation, coronary occlusion, or possibly apart from these. The liability to sudden death is greater in myocardial than in valvular disease. Rupture of the heart, the result of cardiac infarction, is a rare cause. In such cases, death may occur during the first week after coronary occlusion, or later as the result of aneurysm of the ventricle. Of the valvular diseases, sudden death is most frequent in aortic incompetence, almost always due to the occurrence of ventricular fibrillation. In valvular disease, especially mitral, sudden death may result from a large pulmonary embolism. Other causes of sudden death are Adams-Stokes syndrome, and rupture of the aorta in syphilitic aortitis or dissecting aneurysm.

The prognosis is also influenced by the state of the patient's general health and the existence or otherwise of complications, among the latter being arterial disease, hypertension, renal disease, chronic bronchitis, and emphysema.

Finally, the prognosis in cardiac affections should be considered in the light of response to treatment. For example, given a case of severe cardiac failure with auricular fibrillation with a rapid ventricular rate, it is impossible to say what the future will be until full doses of digitalis have been administered.

Having now reviewed the various points which may arise in the consideration of the prognosis of most cardiac affections, these need not be again referred to when the prognosis of individual cardiac disorders comes under discussion.

TREATMENT IN CARDIAC AFFECTIONS

Importance of Treatment in Cardiac Affections.—In few departments of medicine is skilful treatment of so great consequence as in that of cardiac disorders, and in few is it so well rewarded. The heart possesses enormous reserves and, moreover, in recent years there has been a signal

advance in what can be accomplished. I would, therefore, emphasize the importance of a keen, practical interest in cardiological therapeutics. Another observation I would make is that treatment should not only be correct, but sufficiently inclusive and also resourceful.

It is desirable to devote a section to the consideration of the therapeutic measures which may be applicable to any form of cardiac disorder, in order to save much needless repetition when we come to consider the treatment of the individual cardiac affections.

Objects of Treatment.—The primary object is to prevent the supervention of cardiac failure, or complications. With regard to the former, if the view put forward on pp. 851, 852, that its essential cause lies in the heart muscle be accepted, then, on the one hand, the patient should avoid anything which puts a strain upon the myocardium, and, on the other, the practitioner should do everything in his power to promote its efficiency. In addition to the foregoing, cardiac failure, symptoms and complications should receive prompt and suitable treatment.

In the majority of cases the patient's complaint is a manifestation of cardiac failure. In estimating the degree of such, the extent of the departure from his usual standard is of value.

A primary question is whether rest is required and, if so, how much? The ideal is that it should be sufficient to enable the patient to attain his optimum. The amount of rest may vary very greatly. As examples, speaking broadly, in 'slight' cardiac failure, while in some cases it is preferable that the patient should go to bed for a week or so, partial rest for a longer period is usually sufficient. In 'moderate' failure, the patient should remain in bed for at least 3 weeks; and in 'severe' failure, for a minimum of 6 weeks. In a very exceptional case of a woman, aged 55, with very severe exhaustion of the heart, the result of long-continued very excessive work, I advised 6 months' rest in bed, followed by 6 months' partial rest. The subsequent course of events proved the advice to be both necessary and highly successful. The importance of attending to the matter of mental, as well as physical, rest is not sufficiently appreciated.

It should be pointed out that when a patient has had a good period of rest in bed, it should be succeeded by a period of partial rest, the latter having some relation to the former. Thus, if he has been in bed for 4 weeks, he should remain in his bedroom for at least a further week, getting up gradually; he should proceed downstairs and, later, out of doors, gradually; and, in some cases, it is often an advantage to resume work gradually during the first few weeks or more.

I may be permitted to emphasise the following. I have been much impressed with the relatively frequent lack of appreciation of the amount of preliminary rest which is requisite in some cases. This is not a rare cause of unnecessary loss of life. Another and, taking cases in the aggregate, one of the most important causal factors of all, has reference to the future mode of life of patients, with which I shall deal at once.

Instructions regarding Mode of Life.—A cardinal indication is that the patient should live within the limits of his cardiac strength. On the other hand, his usual mode of life should not be unnecessarily restricted, for otherwise he is apt to become nervous and introspective. Herein lies one of the principal duties of the medical attendant. In this regard, it is not

sufficient to tell the patient to 'take care.' The indication is to investigate the patient's occupation, general mode of life, habits, hours in bed, the amount and character of his sleep, how long he takes off for his meals, his mental and emotional character, and other relevant particulars, and to advise, in detail, accordingly.

Each cardiac patient should be in bed for at least 9 hours each night, and have at least an hour for the midday meal, resting after finishing eating, and a quiet day each week. If the degree of impairment is severe, he should be in bed for 10 to 12 hours each night, rest for one or two hours after the midday meal, and stay in bed the whole, or the greater part, of one day a week. The patient should avoid unnecessary tasks outside those of his occupation. When not actually working, he should rest a good portion of the time. Holidays in adequate amount and frequency, and containing a sufficient element of rest are indicated.

With regard to the question of physical exertion, while it is impossible to lay down hard-and-fast rules, it is possible to enunciate a cardinal principle, which will be found of inestimable service, namely: Any exertion which the patient may undergo should not be attended, or followed, by any subjective symptoms, such as breathlessness, palpitation, a sense of tightness or oppression, or discomfort or pain in any part of the front of the chest, fatigue, giddiness, or faintness; or any objective signs, such as maintained increased frequency of the pulse or œdema. This rule will regulate the kind and the rate and the amount of exertion. If any of the foregoing are present during effort, it means that the rate is too quick and it should be proportionately diminished; failing which, that the kind is unsuitable and should be avoided. If they do not occur during it, but subsequently, it means that the amount has been too much and it should be proportionately diminished.

On the other hand, a sufficient amount of exercise is indicated, and any exertion short of producing symptoms is usually not harmful, subject to the following qualifications: it is advisable to keep something in reserve; sudden and violent effort should be avoided; and, in my opinion, based upon personal observations, in aortic incompetence the more strenuous forms of effort should be prohibited in any case.

Here, also, it is not enough to regulate physical exertion only; the importance of attending to the matter of mental effort in cardiac cases is not sufficiently recognised. All excitement, worry and other forms of emotional stress and strain should be avoided.

If the patient suffers from an unduly excitable nervous system, or is prone to worry or be anxious, sedatives, such as a combination of ext. valerian, ext. sumbul, and asafetida, or the bromides, bromide and valerian, uvaleral, or carbromalum, failing which the barbiturates, may be very helpful. My custom is to advise an adequate daily dosage until a full therapeutic effect is obtained, after which a minimal daily dosage for a time. It should not be forgotten that the bromides are strongly cumulative and, especially in the elderly, even moderate doses if taken long enough may produce toxic effects. The matter of sleep is often neglected, and inquiry should invariably be made regarding both its amount and character, and if any defect be found, it should be treated on the lines laid down later.

In most cases the daily amount of fluid taken should be somewhat restricted, the aim being to lessen the amount of work done by the left ventricle

by diminishing its output. The meals should be as dry as the patient will take them, a sufficient amount of fluid being taken between meals. The three meals of the day should be evenly balanced, since a large meal at one time causes too great a variation in the vascular system, to which the heart does not readily adjust itself. The food should be nutritious, easily assimilable, and not likely to cause indigestion. A diet of carbohydrates is bulky, and is apt to cause flatulence and hyperchlorhydria, while a diet consisting of highly nitrogenous food increases the resistance in the peripheral circulation and is equally to be avoided. While, therefore, the diet should be a carefully mixed one, the albuminous element should predominate. Any article of diet which causes flatulent distension of the stomach or bowels should be avoided, since this, by direct pressure, embarrasses the heart and is one of the commonest causes of palpitation. If there is hypertension, see p. 1069.

In cases of ' severe ' cardiac failure, light solids form the best diet, and, as a rule, agree better than fluid food, being less likely to cause flatulence ; the necessary mastication is also an advantage. Care should be taken to ensure that the patient does not take a larger quantity of food than he can comfortably digest. When failure is ' extreme ' the amount of food should be considerably restricted, and only very small quantities at a time, at fairly frequent intervals, should be allowed. Biscuits, small thin sandwiches of potted meat, or small quantities of milk are not infrequently all that can be comfortably digested. Occasionally a pure milk diet is best.

The excessive use of tea, coffee and tobacco should be avoided. It is better for the patient to abstain from alcohol altogether ; but if he has been accustomed to its use and deprivation be a great hardship, a strictly moderate amount may be allowed. Strict attention to the condition of the bowels is advisable. If there is hypertension, a saline each morning and also some mercurial preparation at bedtime once or twice weekly are indicated.

The periodic administration of general tonics is sometimes helpful, especially during convalescence from any illness. Any existing anæmia, obesity, and bronchial catarrh should be treated without fail : the first on account of the myocardium and the tissues in general receiving an adequate supply by oxygen ; and the second because excessive weight involves more work on the part of the heart, and of the tendency to fatty infiltration.

The question of focal sepsis, especially in the teeth, the tonsils, the accessory nasal sinuses, the pharynx, the colon, the appendix, the gall bladder, and the genito-urinary tract, is an important one and should receive attention. Acute infections, especially in chronic valvular disease and congenital morbus cordis, should be guarded against.

Rest.—Rest is of cardinal importance in the treatment of cardiac failure, It is indeed, difficult to exaggerate its value. It is the objective of all therapeutic measures. Details regarding its application are dealt with on pp. 862, 863 and elsewhere.

Systematic Exercises and Massage.—Systematic and graduated exercises are sometimes useful in cardiac affections, provided they are judiciously employed and their effect watched. They are of special help in cases of slight cardiac failure due to the heart muscle being flabby and lacking in tone, as in fatty infiltration. Contra-indications for their use are acute affections of the heart, a severe degree of chronic valvular disease or of

chronic myocardial disease, 'severe' cardiac failure, and cases in which the heart failure is progressive. Simple movements, especially of the Swedish variety, are, in most cases, better than resistance exercises. In all cases such exercises should stop short of inducing any indications of cardiac distress or *maintained* increased frequency of the ventricular rate; and they should be followed by a period of rest. Massage is more often useful than is generally recognised. Vigorous massage may be useful in the case of those who have not the necessary time or opportunity for the usual forms of exercise to keep them in condition. Passive movements and light massage may be employed with advantage in the early stages of convalescence from a period of rest. The same considerations apply as in the case of systematic exercises.

Baths and Spa Treatment.—It is commonly known that immersion of the body in water may exercise a decided influence on the circulation. It is, further, believed by some that certain waters at Nauheim, on account of their ingredients, possess a specific therapeutic value in cardiac affections, but I am very sceptical with regard to this. Patients undoubtedly often derive very great benefit from a stay at Nauheim and at similar spas; but this appears to be due to the rest, the change of air, the regular mode of life and exercise, the careful dieting, and other factors. Given the same conditions of life, equally good results would be obtainable elsewhere. Spa treatment is particularly serviceable in patients who have indulged in excesses of various kinds.

The Digitalis Group of Drugs.—This includes digitalis, strophanthus, squills, convallaria majalis, and apocynum. They have a similar action on the heart, but as digitalis is the most reliable, only strophanthin, which is used for intravenous administration, need also be considered.

With regard to digitalis, the standardized tincture, the powdered leaf, the latter administered in the form of tablets or pills, and Nativelle's digitaline granules are reliable preparations. Fifteen minims (not drops) or 1 c.c. of the tincture is equivalent to 1½ gr. or ·1 gm. of the powdered leaf. The infusion is not advisable, as it is unstable. Digoxin, a pure crystallised glucoside, isolated from leaves of digitalis lanata, is more rapidly absorbed and excreted, and is more stable. Digoxin and strophanthin are extremely irritant if administered subcutaneously or intramuscularly. They are employed intravenously. The latter is a powerful poison in overdosage, and the best therapeutic dose is very near the toxic dose, which does not appear to apply in the case of digoxin. It follows, therefore, whether this preparation should be used or not and, if so, its precise dose, requires most careful consideration. I wish to say, however, that, with these qualifications I have never seen any untoward effects follow its use.

Digitalis is indicated in congestive heart failure—right-sided and in pulmonary venous congestion due to left ventricular failure; and in auricular fibrillation with a rapid ventricular rate and in auricular flutter (see p. 903), even in the absence of congestive failure; in all cases whatever the cardiac lesion may be. The drug is likely to prove far more effective when cardiac failure is associated with auricular fibrillation with a rapid ventricular rate, or auricular flutter with a rapid ventricular rate, than in cases with a rapid ventricular rate associated with normal rhythm. In the former cases the results of its administration in the majority of cases are very, and in some cases extraordinarily, good; it is followed by a rapid

fall in the ventricular rate (Fig. 23) and a concomitant improvement in the general symptoms. When auricular fibrillation, or auricular flutter, is not accompanied by a rapid ventricular rate, there is usually no marked effect. The drug is also likely to be far more beneficial when a lesion is the result of antecedent rheumatic infection. It is to be added that in all cases in which there is an acute infection or a thyrotoxic condition, there may be little or no response to digitalis.

Digitalis is more generally useful in mitral than in aortic cases; in all probability because both auricular fibrillation and congestive heart failure are much more common in mitral disease, and the latter is much more frequently of rheumatic origin than in the case of aortic disease. Formerly the question was often asked whether digitalis should be given in aortic incompetence. There is now general agreement that the answer is in the affirmative, provided the indications mentioned are present. Hypertension and arterial disease are not contra-indications. The drug is contra-indicated in persistent heart-block. Moreover, caution should be exercised and large doses avoided in acute lesions of the myocardium, such as rheumatic carditis, or cardiac infarction.

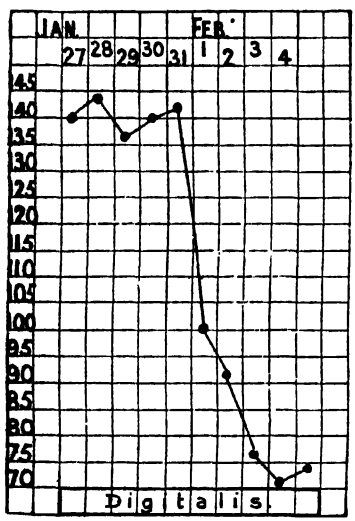

FIG. 23.—Chart showing typical result on the cardiac rate of the administration of digitalis in a case of auricular fibrillation with tachycardia. A drachm of the tincture per diem was commenced on 27th January.

In the great majority of cases the aim of digitalis medication is to accumulate in the body a sufficient quantity of the drug to produce a full therapeutic effect; and, in the majority of these, afterwards to maintain that quantity there. In order to obtain the first object, the intake of the drug should be greater than the amount excreted. Eggleston estimated that in man a total of 1·5 cat units, which equals about 25 minims of the tincture, per ten pounds is required. This amount, however, is too high. For the second purpose, the dosage should be reduced to such an extent as will balance the excretion, with consequent maintenance of digitalization.

In a certain proportion of cases, however, it is not necessary to proceed to full digitalization, a moderate dosage for a period being sufficient and, in the majority of these, improvement can afterwards be maintained without continuing the drug.

If the first method is adopted, with regard to the dosage to commence with, the larger it is the more rapidly is full digitalization produced. The choice of such in any individual case will depend upon the severity and urgency of the patient's condition. For average cases, a good method is to begin with 60 minims of the tincture, or 6 grains of digitalis leaf, and in severe (it should be noted that this word is not synonymous with 'severe' failure described on p. 857) cases, 90 minims of the tincture (or

its equivalent of the leaf) per diem, in each case divided into three or four doses.

In urgent cases, the employment of massive dosage of digitalis by the mouth and the intravenous injection of strophanthin or of digoxin, should be considered. In the first place, these methods are contra-indicated if the patient has already had any of the digitalis group of drugs during the preceding ten days; if the ventricular rate is below 140; unless the patient is in bed and under close observation; and reliable physiological standardized preparations are used.

As regards massive dosage by the mouth, for a patient weighing 10 stone, the following is advised: an initial dose of 1½ mgm. of digoxin, or 90 minims of the tincture, or 9 grains of the powdered leaf, and afterwards, provided there are no toxic symptoms at any time, 1 mgm. of digoxin, or 60 minims of the tincture, or 6 grains of the powdered leaf 6 hours later, and a half dose in another 6 hours. The first-named preparation is to be preferred. Respecting the intravenous method, as stated, I have never seen any untoward effects following strophanthin, but digoxin is preferable. The maximum dose of the former is $\frac{1}{60}$th gr., and of the latter 1 mgm. In the case of each, the drug should be injected very slowly and care must also be exercised to avoid leakage into the tissues outside the vein. In all cases in which either massive dosage by the mouth or intravenous injection has been employed, no more of the digitalis group of drugs should be administered for at least 24 hours, depending on the patient's condition, and when used the dosage should be smaller.

With regard to the respective merits of these two methods, the intravenous is indicated in very urgent cases and massive dosage by the mouth in urgent cases. If, however, there is vomiting, digitalis by the mouth is obviously impracticable. It may be added that the intravenous method may be employed also in urgent or even in merely severe cases, provided in each case the dose is proportionately diminished. But the reader is also referred to the next paragraph.

Digitalis can be absorbed from the rectum, and this method of administration may be used whenever there is vomiting, including in urgent cases when massive dosage by the mouth would otherwise be used and even in those in which it is not necessary to proceed to full digitalization. The dosage is the same as that by the mouth. A simple enema is given a few hours beforehand in order to prepare the bowel for absorption, and the tincture of digitalis should be diluted with warm saline to a bulk of 3 oz., and introduced slowly through a funnel.

With regard to the matter of maintenance dosage, the indication is to ascertain the optimum, *i.e.* the dosage sufficient to control the action of the heart, without at the same time giving rise to any toxic symptoms. This may require weeks or even months of careful observation. It is to be noted that sometimes a relatively small difference in the daily or even weekly dosage is of material moment to the patient's well-being. The patient's own sensations are often helpful and should be taken into consideration in addition to the ventricular rate, which should be counted by auscultation. The optimum dosage may exhibit a wide variation in different patients, but is usually 10 to 30 minims of the tincture, or its equivalent, per diem. In the course of time, variation in the dosage may be found to become necessary. The accumulative action of the drug is apparently not nearly so important

as was formerly believed. At the same time the patient should be watched for overdosage.

Among the indications of overdosage of digitalis are anorexia, headache, nausea, vomiting and diarrhœa. It should be observed that vomiting is not uncommon in cardiac failure apart from the administration of digitalis and, therefore, is not necessarily of toxic origin. The effect of overdosage on the heart may be to produce sinus bradycardia, occasional ventricular extra-systoles, *pulsus bigeminus* or *coupling of the beats* (Fig. 31), a rapid succession of extra-systoles, multifocal extra-systoles, sino-auricular block, auriculo-ventricular block, the ventricular variety of paroxysmal tachycardia, and even ventricular fibrillation. The occurrence of toxic symptoms is an indication to stop the drug until these have ceased and there is a rapid ventricular rate, after which the dosage should be diminished.

Digitalis has no effect upon auricular fibrillation itself; but it diminishes conductivity of the auriculo-ventricular junctional tissues, thereby interfering with the pathway of impulses from auricle to ventricle, and so cutting off some of the too numerous impulses reaching the ventricle, and thus leading to a reduction of the ventricular rate, as a result of which the cardiac contraction becomes stronger, with consequent improvement in the circulation and in the general symptoms.

In auricular flutter, the administration of full doses of digitalis at first usually induces partial heart-block, or an increase in the degree of block already existing, with a resulting diminution of the ventricular rate (Fig. 33). Later, the flutter may cease or auricular fibrillation may be induced. The latter is usually an advantage, because the ventricular rate can generally be more easily controlled by moderate doses of digitalis than in the case of auricular flutter. Auricular fibrillation may persist, or the physiological rhythm may be restored—either event occurring during the administration of the drug or after it has been discontinued. After the restoration of normal rhythm, recurrences of flutter are not uncommon. The same considerations regarding the dosage and method of administration of digitalis (or strophanthus) apply in auricular flutter as in auricular fibrillation with a rapid ventricular rate. For further details, see p. 903.

Cardiac Stimulants.—It is probable that no drug directly stimulates the heart. Nevertheless various drugs which stimulate the respiratory centre and the vasomotor centre are of value in circulatory failure, especially peripheral. Thus, cardiac failure is often accompanied by respiratory failure, resulting in anoxæmia. In such cases, drugs which stimulate the respiratory centre, by causing an increase in the rate and depth of respiration and so helping the venous return to the heart, increase the coronary circulation. Again, stimulation of the vasomotor centre causes an increase in the blood pressure, due mainly to the constriction of the arterioles of the splanchnic area.

Strychnine has a direct stimulant action upon the respiratory and vasomotor centres. But it and camphor—which acts reflexly on the two centres—have been mostly supplanted by nikethamide (coramine) and leptazol (cardiazol), which are powerful direct stimulants of both centres, and are valuable remedies in circulatory failure, particularly peripheral. Caffeine has less action on the respiratory and vasomotor centres than strychnine. Its chief action on the central nervous system is on the psychical areas of the

brain. Its principal peripheral effect is its diuretic action on the kidneys themselves, but as a diuretic it has been replaced by other xanthine drugs. Carbon dioxide is by far the most powerful respiratory stimulant, acting directly upon the respiratory centre, and is sometimes employed as a mixture of 5 per cent. CO_2 in 95 per cent. of oxygen.

Cardiac stimulants are of special value in peripheral circulatory failure.

Diffusible stimulants (ether, ammonia and alcohol) reflexly stimulate the respiratory and vasomotor centres, and are frequently useful in an acute emergency.

Dextrose is of value in conditions of circulatory collapse, such as may follow coronary thrombosis, and possibly in congestive heart failure. It is a form of nutriment which is rapidly absorbed and easily metabolised. It may be given by the mouth, by the bowel, or intravenously. One pound of dextrose dissolved in 2 pints of water and flavoured with orange or lemon juice forms a convenient concentrated solution, which may be given diluted to taste. For intravenous injection, a hypertonic solution is advocated, and 100 c.c. of a 30–50 per cent. solution may be administered.

Insulin, in conjunction with dextrose, is held by some to be of value in congestive heart failure and also in angina pectoris. With regard to the former, most benefit is to be expected when there is evidence that a defect of myocardial nutrition underlies or aggravates the condition. Five units of insulin subcutaneously, followed in 15 minutes by 50 g. of dextrose or lævulose by the mouth, is given once daily. This may be continued for a week, the dose of both being then doubled if no improvement results. This form of treatment may be employed concurrently with the administration of digitalis. Respecting angina pectoris, see page 989.

Diuretics.—If in congestive failure the response to rest, the digitalis group of drugs, and other methods of treatment is not quick or adequate, primary diuretics are, in addition, indicated. These include the xanthine group (theobromine, theophylline, and caffeine); the saline diuretics (potassium acetate and citrate, and sodium citrate); and the organic mercurial compounds.

At the outset I would point out and emphasise that it is advisable periodically to alternate the diuretics and also that a combination is sometimes more effective.

A combination formerly much used is pil. digitalis co., which consists of pulveris digitalis, pulveris scillæ and pilulæ hydrargyri, āā gr. 1.

Theobromine, gr. 5–10, is a powerful diuretic, but as it is very insoluble in water its absorption is slow so that it is not much employed. Theobromine and sodium salicylate (diuretin) is freely soluble, and is therefore used instead, the dose being gr. 10–20. Theophylline (theocine) is still more potent, but because of its lack of solubility is not used, theophylline and sodium acetate, gr. 2–5 being used instead. Both are apt to cause gastric disturbance. Aminophylline (euphyllin) is supposed to be as powerful as theophylline, and is more soluble and therefore more rapid. The dose is gr. 1½–3. It may also be employed by the rectum, intramuscularly, or intravenously. Caffeine is not much employed as a diuretic, having been largely supplanted by the other members of this group. It is used more as a stimulant.

Organic mercurial preparations are incomparably the most potent primary diuretics in the treatment of congestive cardiac failure, and their

discovery constitutes a striking advance in cardiological therapeutics. I would emphasise their very great value in suitable cases, for they are frequently successful when digitalis and other diuretics fail. They are especially indicated in severe cases, or when a rapid effect is desired. They are also of value in cases of chronic adhesive pericarditis with recurrent ascites. Digitalis may be given at the same time. It is necessary to point out that, owing to their high mercury content, they may give rise to symptoms of mercurial poisoning, such as stomatitis, severe colitis, with bloody diarrhœa, or hæmaturia. They should not be employed in acute nephritis, or severe impairment of kidney function, or hæmaturia, or enteritis, but a moderate degree of albuminuria, such as is common in heart disease, does not contra-indicate their use.

Novasurol is by far the most toxic, and its use has been abandoned in favour of the injection of mersalyl (salyrgan) which is safer and little, if at all, inferior in diuretic potency. It is administered either intravenously or intramuscularly. In either case a preliminary dose of 0·5–1 c.c. is given. If no toxic symptoms supervene, doses of 1½ or 2 c.c. may be repeated at intervals of 2 or 4 days. Or the drug may be administered once weekly for long periods to ambulant patients. Recently suppositories have been introduced, and are not far short as effective as the other two methods.

These diuretics are best administered the first thing in the morning in order to avoid the patient's sleep being disturbed. A profuse diuresis usually commences shortly afterwards and continues for 24 to 48 hours; and often 10 to 20 pints of urine may be passed within 48 hours. It is important to restrict the daily intake of fluid to within 40 oz. and occasionally even 30 oz. Moreover, the total amount of urine passed each 24 hours should be carefully measured, and it is also advisable to weigh the patient at the commencement of the treatment and at weekly intervals, a reduction in weight being a valuable criterion of the efficacy of the treatment. The diuretic effect of the drugs is increased by the administration of an acid-producing salt, such as ammonium chloride or nitrate. Thirty grains in solution by the mouth thrice daily for two or three days previously is the appropriate method.

QUINIDINE.—Quinidine is employed in the treatment of persistent auricular fibrillation and persistent auricular flutter, especially the former, with the object of arresting either condition—in other words, to restore the normal rhythm. It is also used in paroxysmal tachycardia, paroxysmal fibrillation and paroxysmal flutter, in the intervals between the attacks, to prevent their recurrence.

Quinidine is a cardiac depressant, and it acts directly on the auricular muscle and by depressing the vagus. It prolongs the refractory period of auricular muscle and slows the conduction rate. Prolongation of the refractory period tends to interrupt the circus movement in the auricles (see p. 897), while slowing of conduction favours its continuance. Where the action on the refractory period predominates, the circus movement is abruptly terminated and the normal rhythm is restored. The slowing of the rate of the circulating wave in the auricles tends to increase the frequency of the ventricular response, so that the ventricular rate rises during quinidine administration, before normal rhythm returns. This tachycardia may be prevented to a large extent by giving a preliminary course of digitalis before commencing quinidine. Extra-systoles may be observed after the auriculae

fibrillation has ceased, and may give rise to palpitation. They occur as a general rule only when the auricular rate has diminished considerably, generally to 250–300 per minute. Their appearance is an indication of poisoning. In successful cases of auricular fibrillation, the sequence of events is auricular flutter, transient arrest of the whole heart, and the restoration of the normal rhythm.

General toxic symptoms, cardiac failure, and embolism may occur during the administration of quinidine. Among the first are headache, giddiness, tinnitus, transitory visual disturbance, nausea, vomiting, abdominal pains, palpitation, præcordial pain, sweating, scarlatiniform or morbilliform rashes, urticaria, a mild degree of pyrexia, fainting attacks, and mental symptoms. Among the manifestations of cardiac failure are sudden collapse, sudden cessation of respiration, severe dyspnœa, cyanosis, and disappearance of the pulse—due to ventricular standstill during the transition stages. The risk of embolism occurs at the time when the auricle first commences to contract again after the restoration of the normal rhythm. Thrombi are expelled from the auricular cavity into the systemic or pulmonary circulation, and death may result. Death during the administration of the drug may be due to cardiac failure or to embolism.

In persistent auricular fibrillation the normal rhythm can be restored in at least half of suitable cases. Relapse occurs, sooner or later, perhaps in a majority of these. In my experience this can be avoided in a large proportion of cases by a gradual diminution of the total daily dosage and, later, the continuation of a small daily dosage for some time. Quinidine is less successful in restoring the normal rhythm in auricular flutter than in auricular fibrillation.

In persistent auricular fibrillation, or persistent auricular flutter, quinidine is most likely to be successful in those cases in which there is at the most only a moderate degree of valvular or myocardial disease, of cardiac enlargement, and of cardiac failure; in those in which the abnormal rhythm is the result of antecedent rheumatism or chorea; in cases in which there is an absence of acute endocarditis, or acute myocarditis; when the onset of the condition has occurred during an acute infection—such as influenza; when the abnormal rhythm has followed paroxysmal attacks; when of recent origin; and in the case of the young. It is particularly useful in hyperthyroidism. Contra-indications for the use of the drug are the presence of a severe grade of valvular disease, or of myocardial disease, great enlargement of the heart, a severe degree of cardiac failure—unless this is remedied by a course of rest and other therapeutic measures—heart-block, existing or recent acute or subacute endocarditis or myocarditis, a recent history of embolism, and in those cases when the patient cannot be confined to bed and be assiduously and carefully watched.

A preliminary course of rest in bed and of digitalis medication is advisable. It is the practice of some to stop the digitalis for a few days before commencing quinidine, while others continue its use during the administration of the latter, in order to control the rapid ventricular rate. The patient should invariably be confined to bed, absolute rest, physical and mental, should be enjoined, and he should be assiduously watched. Frequent electro-cardiographic examinations are very advisable. It is advisable to give a single dose of 5 grains, or two doses of 3 grains at an interval of 2 hours, to

test for possible idiosyncrasy, and if none is found to exist, to commence the routine treatment the following day. Five grains three times daily may be commenced with, and the total daily dosage increased by 5 grains each day up to 30 grains, not exceeding four divided doses in the 24 hours, which may be continued for a week, or until normal rhythm is restored, or symptoms of intolerance appear. The majority of successful cases follow the use of only small doses of the drug, and its use is rarely successful if more than 30 grains per diem are required. The drug should be stopped if severe toxic symptoms, severe cardiac failure, or embolism, occur, or if there is an auricular rate of 250 or 240 per minute—because of the risk of inducing 1 : 1 rhythm, or, as a rule, if there is a ventricular rate above 160. After the normal rhythm has been restored, the total daily dosage should be diminished by 5 grains each day to 5 grains twice, or even once, daily, and this continued for some months unless found to disagree with the patient. This method lessens the likelihood of relapse.

When quinidine is employed in paroxysmal tachycardia, paroxysmal fibrillation, or paroxysmal flutter, in the intervals between the attacks to prevent their recurrence, the dosage is 5 to 15 grains per diem.

Oxygen.—Oxygen is sometimes of value in cases of cardiac failure. The chief indications for its use are cyanosis and dyspnœa, but in the case of the former not if due to peripheral stasis. It should be administered continuously, it may be by means of a nasal catheter, an oxygen tent, or an oxygen mask. As a rule the last is uncomfortable, but recently (1938) a very efficient apparatus has been introduced in America by Boothby, Lovelace and Bulbulian, and may now be obtained in this country as the "B.L.B. inhalation apparatus."

Venesection.—This method of treatment is sometimes neglected when it might be employed to advantage and be even life-saving. It is indicated when there are manifestations of great distension of the right chambers of the heart—as, for example, cyanosis, turgescence of the veins of the neck, severe dyspnœa, an enlarged and tender liver, and increased area of impairment of the percussion note to the right, and also in acute pulmonary œdema, in either case especially if there is hypertension. As a rule it is contra-indicated in hypotension and anæmia of pronounced degree. Venesection may also be very useful when the blood pressure is much raised. The median basilic vein should be chosen, and 10–20 ounces withdrawn. If venesection is not practicable, 6–8 leeches over the right ventricle or liver may be of service.

Total Thyroidectomy in the Treatment of Congestive Heart Failure.—The number of cases with congestive heart failure in which total ablation of the thyroid has been performed is now sufficient to permit the evaluation of this procedure as a therapeutic measure in the treatment of heart disease. The results to hand already indicate that great discrimination should be exercised in the selection of cases, this requiring the most careful consideration respecting diagnosis and prognosis. It should at once be evident that this procedure should only be considered when the medical methods of treatment have been fully tried and have failed; if the operation is likely to result in improvement; and when the operative risks are not unreasonable. With regard to the last, results have established that the presence of renal impairment, chronic lung disease, and intractable œdema, add so materially to the risks connected with the operation as to contra-

indicate this form of treatment. On the other hand, the presence of hypertension does not appear to be a contra-indication, but in no instance has the operation brought about an appreciable lowering of the blood pressure. The therapeutic value of the operation corresponds with the lowering of the basal metabolism. When this is reduced to minus 30 per cent., myxœdema frequently develops, but this condition responds to small doses of thyroid without materially detracting from the improvement which has been obtained by the diminution of the basal metabolism. With a fuller and more widespread appreciation of the value of the organic mercurial diuretics, the question of this form of treatment does not arise as frequently as would otherwise be the case. Even so, it is now and again indicated in carefully selected cases.

Treatment of Symptoms

The indications for and the methods of treatment already described should be considered.

Sleeplessness.—The ventilation of the bedroom should receive attention, and, while the patient should be kept warm, the bedclothes should not be heavy. It should be remembered that insomnia may be due to dyspnœa, and in these cases the patient is sometimes troubled with 'night starts' as he is falling off to sleep; the dyspnœa should be treated on the lines to be laid down later. Sedatives (as described on p. 863) may be sufficient for sleeplessness. Failing these, or as an alternative to such, paraldehyde (suitably flavoured), chloral and bromide, or the quickly acting barbiturates (alone or in combination with bromide). The first is a valuable drug in many cases, especially when there is dyspnœa. If the patient is more restless or excited after taking the drug, it usually means that the dose has been too small. Chloral hydrate has the reputation of being a dangerous remedy in heart disease, especially in chronic myocardial disease, but I have used it very extensively and have never found this to be the case. It produces a refreshing sleep, and is especially useful when nocturnal dyspnœa or hypertension is present. It may be given in doses of 5 to 10 grains by the mouth, gradually increasing to 15 or even 20 grains if necessary, the dose being repeated in 2 hours if required, and the effects carefully watched. If these drugs fail, resort should be had to opium or one of its derivatives, which are especially useful when there are accompanying restlessness and dyspnœa, and are particularly necessary in cardiac asthma and coronary occlusion. In some cases a combination of bromide, chloral and tincture of opium suffices. The hypodermic administration of morphine is much more efficacious than when given orally. It is well to commence with small doses, for example, $\frac{1}{4}$th grain, and gradually to increase to $\frac{1}{2}$th grain, or even more, until relief is obtained, the effects being carefully watched. Cyanosis is not an absolute contra-indication to the administration of chloral, opium or morphine. Speaking generally, these drugs should not be administered in those cases in which there is much bronchial secretion, or œdema of the lungs, or in Bright's disease; but in individual cases they may be tried if the first dose be very small, and the dosage be subsequently increased with great caution. Further, when there is much bronchial secretion, or œdema of the lungs, a sharp look-out should be kept to see whether the administration

of the drug increases them; in such a contingency, atropine or strychnine should be administered in combination with the morphine.

CONGESTIVE FAILURE AND ŒDEMA.—The measures which are of particular value are the restriction of the daily amount of fluid, the digitalis group of drugs, and primary diuretics. If œdema of the lower extremities is slight, bandaging is often useful, and this may be combined with massage. If it is severe and does not respond satisfactorily to the measures mentioned, the mechanical removal of fluid by Southey's tubes or multiple punctures, preferably the former, should be considered. It should be performed under strict aseptic precautions, and the patient should be in the sitting position in order to obtain a full beneficial result. If pleural effusion or ascites, especially the former, does not yield to other treatment and causes embarrassment, the fluid should be withdrawn.

CARDIAC ASTHMA.—Sleeping in a more upright position may be of help as a prophylactic measure. If an attack occurs, the patient may be most comfortable when supported by high pillows or a bed-rest, or he may not be able to breathe with comfort even in bed, and may prefer to sit up supported in a large easy chair, perhaps leaning forward and supporting himself with his arms on the back of another chair. Diffusible stimulants, the nitrites—especially if there is hypertension, and oxygen are sometimes of value. Morphine (gr. $\frac{1}{6}$–$\frac{1}{4}$) with atropine (gr. $\frac{1}{100}$) hypodermically is the most effective measure. Adrenaline is recommended by some. If there are manifestations of great distension of the right side of the heart, or the blood pressure is much raised, venesection is indicated. If the condition persists, massive dosage of digitalis by the mouth, or the intravenous injection of digoxin or strophanthin should be considered (see p. 867).

PULMONARY ŒDEMA.—Dry cupping is sometimes beneficial in chronic pulmonary œdema. If an attack of acute pulmonary œdema occurs, a hypodermic of morphine, gr. $\frac{1}{4}$, with atropine gr. $\frac{1}{75}$–$\frac{1}{50}$th, should be administered immediately. Oxygen is often found to cause restlessness. The same considerations as regards venesection and digitalis therapy apply as in the case of cardiac asthma.

SYNCOPE.—It has been noted on p. 854, that this complication may be cardiac or peripheral in origin. The treatment of syncope is divided into prophylactic and immediate. With regard to the first, the ætiology should be reviewed. Heated rooms, crowds and prolonged standing should be avoided. If syncope occurs, the patient's head should be lowered and the clothes loosened at the neck. Plenty of fresh air is indicated. Diffusible stimulants (ether, ammonia or brandy) should be given by the mouth. Failing these, strychnine (gr. $\frac{1}{30}$–$\frac{1}{20}$th), or nikethamide administered subcutaneously or intramuscularly. See also Adams-Stokes Syndrome (p. 909), and Acute Peripheral Circulatory Failure (p. 875). In vasovagal attacks, atropine, failing which, adrenaline, should be injected subcutaneously.

PALPITATION.—This is a malady in which it is particularly important to investigate thoroughly and treat the cause; among these, digestive disturbances and toxic conditions are especially to be noted. Local applications, such as a belladonna plaster, or lin. bellad. c. chlorof., may be helpful. If these measures fail, sedatives (see p. 863) should be tried.

CARDIAC PAIN.—As in the case of palpitation, the ætiology should be reviewed. If there has been overstress, rest is indicated. A belladonna

plaster, or lin. bellad. c. chlorof., applied to the præcordium may be beneficial; while sometimes—especially in acute inflammatory conditions—the employment of hot fomentations or poultices, an ice-bag or Leiter's coil, a mustard leaf, or leeches may afford relief. If these measures fail, sedatives (see p. 863) may be administered, and in the event of their not being successful it may be necessary to resort to opiates.

VOMITING.—Milk is, in the majority of cases, the best food, to which sodium citrate (15 grains to each 10 ounces) may be added. If milk be not tolerated, peptonised milk, whey, albumin water, milk gruel, koumiss, or strong meat essences may be sipped, the patient not being allowed any solid food. A brisk purge should be administered, and bismuth with hydrocyanic acid may be given. Counter-irritation over the epigastrium is occasionally of some help for the relief of vomiting. If, in spite of these measures, the vomiting still continues, all food, and even water and drugs, by the mouth should be stopped, and resort be had to rectal feeding. The advantage in these cases of rectal feeding with milk pancreatised for at least 24 hours is not sufficiently recognised.

TREATMENT WHEN ACUTE PERIPHERAL CIRCULATORY FAILURE IS PRESENT

This comprises the following: Lowering of the patient's head, raising the foot of the bed to the extent of 1 or 2 feet, and the application of a tight binder to the abdomen. Diffusible stimulants. Saline and dextrose by the rectum, or intravenously. Strychnine, nikethamide (coramine), adrenaline, ephedrine, cardiazol-ephedrine, and pituitary (posterior lobe) extract ($\frac{1}{2}$–1 c.c.), or in the case of pregnancy, pitressin ($\frac{1}{2}$ c.c.).

Having discussed the various therapeutic measures which may be applicable to any form of cardiac disorder, these need not be again referred to when we come to consider the treatment of the individual cardiac affections: in this way much repetition will be saved.

FREDERICK W. PRICE.

FUNCTIONAL DISORDERS OF THE HEART

By functional disorders of the heart are meant those which occur independently of any structural change, whether of the valves, the myocardium, or the arteries; they are merely disorders of function, no organic lesion being necessarily present. It should be remembered, however, that any variety of functional disorder may be found in association with, though independent of, organic disease, especially if cardiac failure be present; and, further, that a persistent functional disorder may terminate in organic disease, although not necessarily so. Some writers deny the existence of functional disorder of the heart, being of opinion that in every case some structural change not only exists but accounts for the malady. Such a view is, in my opinion, untenable. I would, however, emphasise that not infrequently a diagnosis of functional disorder is erroneously made owing to the fact that the existence of organic disease has not been detected. As far as my experience goes, this applies especially to chronic myocardial disease unaccompanied by chronic

valvular disease, arterial disease, and perhaps slight mitral stenosis and chronic adhesive pericarditis. The first is referred to on page 949. With regard to the second, how often is arterial disease excluded as the result merely of the examination of the radial artery? Not only the radial, but at least the brachial, the temporal and the retinal arteries, and the aorta, should be examined.

Among functional disorders may be included palpitation, cardiac pain, irritable heart of soldiers, primary cardiac strain, sinus tachycardia, sinus bradycardia, and some cases of irregular action of the heart. No doubt some of these disorders may be either functional or due to organic disease. With regard to irregular action of the heart, it depends upon the type. It is almost universally agreed that sinus irregularity is always functional. Extra-systoles may or may not be due to some structural change in the myocardium. In the majority of cases, auricular flutter and auricular fibrillation are indicative of some myocardial change. It is true that cases of auriculo-ventricular block have been recorded in which there was an absence of any demonstrable lesion of the junctional tissue; but in some of these the vagus was found to be affected.

PALPITATION

By palpitation is meant the consciousness of the cardiac impact against the chest-wall, whether there is an increase in its rate or not, and whether the cardiac action is regular or not. I shall not deal here with those cases which are the result of extra-systoles, paroxysmal tachycardia, auricular flutter, auricular fibrillation, or heart-block.

Ætiology.—While palpitation may occur in organic disease of the heart, perhaps especially in aortic incompetence and cardiac hypertrophy from any cause, it is more frequently met with apart from this. It is more common in females. Among other causes are digestive disturbances—especially when attended with flatulent distension; the excessive indulgence of tea, coffee, tobacco or alcohol; neurasthenia and emotional states, the menopause, and the period of menstruation; during convalescence from any acute illness; thyrotoxicosis; and what is called disorderly action of the heart. The immediate cause of an attack is usually emotion, but it may be excessive physical exertion.

Symptoms.—The attack may last from a few seconds to a few hours. It is usually gradual in onset and passes off gradually. The subjective symptoms vary from a sensation of a gentle impact to the consciousness of a violent one against the chest-wall and actual pain in the præcordium in the severer forms. There may be flushing of the face, a sensation of throbbing in the head, and giddiness or faintness. The pulse is generally increased in rate, and its character may resemble that of the pulsus celer. The larger arteries, such as the carotid, may exhibit pulsation. The apex-beat is commonly diffuse, and its force increased, with a quickened outthrust. The heart is found to be not enlarged. The cardiac sounds are increased, and may be short and sharp. There may be a systolic murmur in the pulmonary area and less frequently at the apex. In dyspeptic patients, relief may coincide with the eructation of a large quantity of gas.

Treatment.—This is dealt with on p. 874.

CARDIAC PAIN

Discomfort or pain in the præcordium in the majority of cases is of extrinsic origin. This is especially so in females. It may be met with in neurasthenia and emotional states; digestive disorders, including of the gall-bladder, in all cases particularly if accompanied by flatulent distension of the stomach or colon; in general debility; during convalescence from an acute illness; toxic conditions; and in Irritable Heart.

Pain of extrinsic origin is more frequently related to emotion or mental effort, especially the former, than to physical exertion; it is in the great majority of cases situated in the præcordium, and usually over a smaller area of this than in the case of cardiac failure; it occasionally extends to near the angle of the left scapula or left armpit, or rarely to the left arm or over a larger area of the left front chest and even up to the neck; is either of a dull aching or of a sharp stabbing character; and is of shorter duration than in the case of cardiac failure. There may be hyperæsthesia and tenderness. Other symptoms, particularly connected with the nervous, vasomotor and alimentary systems are often present. Treatment has been discussed on p. 874.

Pain indicative of cardiac failure is referred to physical or, less frequently, mental effort, but it may not come on until some hours have elapsed; it also in the great majority is situated over the præcordium, and generally over the greater part or the whole of it; it is almost always confined to this area; is of a dull aching character; and is more or less continuous.

Treatment has been discussed previously.

The pain of angina pectoris is described on p. 987.

IRRITABLE HEART OF SOLDIERS

Synonyms.—Soldier's Heart; Disordered Action of the Heart (D.A.H.); Effort Syndrome; Neuro-circulatory Asthenia.

This is a condition which is characterized by a combination of symptoms due to a subnormal circulatory system—including, if not especially, the peripheral variety—and a subnormal nervous system.

The irritable heart of soldiers was first described by Myers (1870) and Da Costa (1871) in the United States of America. During and after the War of 1914–1918 much attention was paid to the subject in this country, owing to the large number of soldiers who were invalided home for so-called valvular disease of the heart and other cardiac disorders. The malady was first called irritable heart of soldiers, and, during the War of 1914–1918, soldier's heart, or disordered action of the heart (D.A.H.), and, later, by Lewis, effort syndrome. In the United States it is now termed neuro-circulatory asthenia. It is to be observed that the affection is not synonymous with athlete's heart or primary cardiac strain (see p. 880).

It is necessary to point out that what is called irritable heart of soldiers does not differ from that which is met with in civilian life.

Ætiology and Pathology.—The condition is more common during adolescence and up to early middle life, in poorly developed subjects, in those of a sedentary or light occupation and are out of training, and in urban life.

In the case of soldiers, it was formerly thought that the cause was either the accoutrements, such as tight belts and closely fitting uniforms, or over-exertion, such as "setting-up drill." It was found, however, that the correction of these did not obviate the malady.

It is now believed that a number of factors acting together, some more than others, constitute the cause. These include congenital or developmental weakness of the circulatory and nervous systems, a poor physique, a sedentary or light occupation, excessive physical exertion, an unsuitable kind of training, mental or emotional stress or strain, lack of sleep, infection, in a small percentage of cases hyperthyroidism, and, in my opinion, excessive smoking, especially of cigarettes.

An individual born with subnormal circulatory and nervous systems finds by experience that while he is able to engage in ordinary physical and mental effort he is incapable for those of a strenuous character. He arranges his manner of life accordingly, and consequently developmental weakness becomes superadded. Naturally such an individual does not stand the usual training so well as do those who were engaged in heavy or moderately heavy employments. Even with a slow and very carefully graduated training, he may never be able to engage in severe physical or mental effort. It is difficult to say how much physical stress or strain alone is an ætiological factor. Not infrequently there is a recent history of infection, either chronic, such as focal sepsis or pulmonary tuberculosis, or an acute infective disease.

Lastly, it is to be noted that the affection may be met with in those with organic disease of the heart.

Symptoms.—The onset is usually gradual. The commonest symptoms are breathlessness, palpitation, exhaustion, præcordial discomfort or pain, giddiness, and nervousness. Generally the shortness of breath, palpitation, and discomfort or pain are related to physical exertion or emotion; the sense of exhaustion to physical or mental effort; and the giddiness especially to change of posture. Breathlessness and palpitation may be very easily induced, and may also be present while at rest. The pain is commonly limited to the præcordium but sometimes radiates to near the angle of the left scapula, or rarely to the left arm or over a larger area of the left front chest or up to the neck. It is generally of a dull aching character but occasionally is sharp and stabbing. There may be hyperæsthesia and tenderness.

There may be faintness, and occasionally actual syncope, the latter probably being of the vasovagal type and more often in the young. Vasomotor symptoms, such as coldness and pallor or lividity of the extremities, and a tendency to sweating and flushing, are not infrequent. There may be lassitude, depression of spirits, irritability, loss of emotional control, insomnia, tremors of the hands, and headache, the last especially after exertion.

During sleep the cardiac and respiratory rates are normal. When the patient is awake but at rest they may be increased and there may be a slight increase in the blood pressure. There is frequently an abnormal response in the cardiac rate and the blood pressure with the assumption of the upright posture after lying down. The cardiac and respiratory rates and the blood pressure are unduly and it may be markedly increased by exertion, and, though perhaps to a less extent, by emotion, and their return to the former level after such is delayed. The apex-beat is often diffuse and its force increased, but the out-thrust is quicker and shorter than normal—which is

the opposite to that which obtains in hypertrophy. On X-ray examination, the heart is found not to be enlarged. The first sound may be increased in loudness, and may also be short and sharp. There may be cardio-respiratory murmurs (see p. 939), or a systolic murmur in the pulmonary area or at the apex, especially the former, in which case the murmur is generally harsh and may give the impression of being superficial. Reduplication of the second sound, it may be only after exertion or on lying down after such, is occasionally to be observed, and if present is indicative of cardiac strain (see p. 881).

Diagnosis.—It is necessary to diagnose the condition from chronic valvular disease, cardiac hypertrophy, focal sepsis, pulmonary tuberculosis, hyperthyroidism, and primary cardiac strain. This may be done by a consideration of the features described. In hypertrophy, the out-thrust of the apex-beat is slower and longer than normal; there is evidence of enlargement of the heart; and the first sound may be long, low in pitch and muffled. Primary cardiac strain is referred to on p. 881.

Prognosis.—As far as the duration of life is concerned, it is favourable. As to the course of the malady, this varies very considerably, and a period of observation is required to attempt a reliable opinion. The outlook is affected by the ætiological factors, the physical and, it may be especially, the mental make-up of the patient, probably most of all by the therapeutic measures adopted, the response thereto, and perhaps by the age of the individual. In the case of a chronic infection, it depends upon whether this can be removed. When the condition follows an acute infective disease, the prognosis is favourable provided convalescence is not hurried. This also applies when the affection is chiefly due to an anxiety condition, and suitable and competent psychological treatment is employed. The prognosis is probably better in the young.

Taking cases as a whole, the proportion of those who will not be able to engage in the physical and mental activities previously possible without experiencing some abnormal symptoms is by no means negligible.

Treatment.—PROPHYLACTIC.—In those of poor development, or of sedentary or light occupation, a slow and very carefully graduated training is of fundamental importance.

CURATIVE.—Reassurance and encouragement are of prime significance. In severe cases a preliminary rest in bed, of moderate duration, is usually helpful. If mental strain has been a factor, freedom from mental work until the patient has attained his optimum is advisable. Due attention to the cause of the malady, such as focal sepsis or an anxiety state, is obviously indicated. Psychotherapy has been spoken of under Prognosis. If there has been excessive indulgence in tobacco, smoking should be avoided altogether; and even if there has not, at the most it should be strictly moderate in amount. Alcohol is better avoided.

Efforts should be directed towards the restoration of the patient's general bodily and mental health. To this end careful attention to the matter of sleep, an ample amount of nutritious food, fresh air, slow and very carefully graduated exercise under wise supervision—preferably in the open air and, if the patient is fit for such, at first in the form of games—always stopping short of abnormal subjective symptoms, and breathing exercises are enjoined. Massage is not infrequently of help, and hydrotherapy is occasionally so. If the patient suffers from an unduly excitable nervous system, or is prone

to worry or be anxious, sedatives (see p. 863), in small daily dosage, are indicated for a time, and may be repeated occasionally if found to be required. Periodic courses of general tonics are worth a trial. Digitalis is of no avail and may even do harm.

PRIMARY CARDIAC STRAIN

By primary cardiac strain is meant a cardiac disorder which is the direct result of excessive physical exertion in an individual whose heart was previously sound.

It should be pointed out that most cardiologists are of opinion that physical exertion alone cannot cause such. They believe that in all cases the myocardium is weakened by toxins, either bacterial or chemical, or disease. Together with some cardiologists and general physicians, and pathologists of great authority, I do not share this view. At the same time I wish to make it clear that formerly physical exertion as an ætiological factor was very much exaggerated.

Ætiology and Pathology.—The affection is more likely to occur in middle or later life, and in those not in training. It may be due to sudden and violent physical exertion, such as boat-racing, and athletic and boxing contests; or the result of very severe, and either long continued or frequently repeated muscular effort, such as in heavy manual labour and in athletic training.

Regarding the first, when the heart is called upon for an increase of work by physical exertion, there is stretching of the muscular fibres and dilatation of the cavities together with an increased output of blood. Under normal conditions, the dilatation is temporary and physiological. In violent and sudden muscular exertion, however, it may persist, *i.e.* there is pathological acute dilatation. With rest in bed, the cavities usually gradually return to the normal, but functional disability may continue for some time.

Respecting the second, when the heart has to do continued extra work, cardiac hypertrophy takes place. If the physiological limits of the latter in any particular individual have been reached, any further demand on the organ will, sooner or later, have a permanent deleterious effect and pathological dilatation may take place. As regards this second group, it may be mentioned that those who do not believe that long continued very severe physical exertion alone can cause strain, quote the example of the horse. It seems to me that to compare, in this respect, man with an animal whose natural primary function and almost the whole of his activities have to do with physical exertion is hardly appropriate.

Symptoms.—When the malady is due to sudden and violent effort, there may be lividity or cyanosis of the face, giddiness, and vomiting; later, there may be collapse, quickened shallow breathing, coldness of the skin, præcordial uneasiness or actual pain, and a quickened, small and thready pulse; while later there may be indications of pronounced acute cardiac dilatation. The last involves both sides of the heart, but if the exertion has entailed severe fixation of the walls of the chest, the dilatation is chiefly right-sided, while if it has involved great contraction of the muscles, it is principally left-sided.

In the chronic forms of the affection, among the symptoms are shortness of breath, palpitation, giddiness or faintness, a feeling of weight or oppression, and discomfort or pain in the chest, the last sometimes extending to the left scapular region or arm. The pulse is usually small and weak, and its rate increased even while at rest. The area of cardiac impairment is not infrequently increased to the left and sometimes also to the right. The cardiac sounds may be feeble, or short and sharp, there may be a mitral or tricuspid murmur, and the second sound in the pulmonary area may be accentuated. Reduplication of the second sound, it may be only after exertion or on lying down after such, is sometimes present, particularly in the young, and is probably due to dilatation of the left ventricle.

Diagnosis.—This in large measure resolves itself into the question whether the case is one of primary cardiac strain, or whether the heart has been previously damaged; in the latter case, excessive physical exertion is merely the exciting cause of the malady. In considering this problem, a previous history of one of the causes of morbus cordis and evidence of myocardial or valvular disease are obviously of material importance.

Reduplication of the second sound, if present, is a valuable sign of primary cardiac strain.

There are certain fundamental distinctions between primary cardiac strain and irritable heart of soldiers. This is readily recognised by a comparison of the respective clinical features described (see pp. 878, 879).

Prognosis.—This exhibits a wide variation. In the young and robust, in the less severe cases, full recovery is the rule. This may occur in a few days or weeks, but on the other hand progress may be slow. Occasionally, however, recovery is not complete, the individual never being able to engage in physical exertion previously possible without experiencing some abnormal symptoms. In the more severe cases, the latter is not infrequent.

In middle or later life, even in the less severe cases, progress may be very slow, and full recovery is infrequent and perhaps only occasional; while in the more severe, even the duration of life may be shortened.

In all, a diminishing increase of pulse-rate is a favourable omen.

Treatment.—In the acute cases a very hot bath is to be commended, the patient being lifted out of it in a blanket, together with the administration of a few 15-grain doses of theobromine and sodium salicylate (diuretin). In the early stages, a strictly limited amount of food, both solid and liquid, is indicated. Oxygen may be required in some cases. When the patient is fit to get up, great caution should be exercised with regard to physical exertion. Warm baths, followed by a cold douche, may be tried provided there is a quick reaction.

In the chronic more severe cases, prolonged physical and even mental rest may be necessary. Massage, under certain conditions (see p. 864), may sometimes be of advantage, even in a comparatively early stage.

SINUS TACHYCARDIA

By the term tachycardia is meant an acceleration of the cardiac rate. There are two main varieties, namely: (1) sinus tachycardia; and (2) paroxysmal tachycardia. In addition, there is tachycardia in most cases of

auricular flutter and of auricular fibrillation. In the sinus variety the tachycardia is due to an increase in the function of rhythmicity in the sino-auricular node. In paroxysmal tachycardia, on the other hand, the tachycardia is the result of an abnormal rhythm, the impulses arising at some site other than the sino-auricular node. We shall here deal with sinus tachycardia. Paroxysmal tachycardia is discussed on p. 891.

Ætiology.—Sinus tachycardia may be physiological. In some healthy individuals the cardiac rate is persistently rapid. It is, therefore, difficult to decide when an increase of the cardiac rate in an individual is pathological; in this connection a record of the past history is of value. Transient sinus tachycardia may be a physiological reaction to emotional excitement, physical exertion, and the ingestion of food.

The pathological form of tachycardia may occur both during and after acute infective diseases, during convalescence from any acute illness, in pulmonary tuberculosis, focal sepsis, thyrotoxicosis, the excessive use of tea, coffee, tobacco or alcohol, and cardiac failure. It is also met with in irritable heart of soldiers, neurasthenia and emotional states, subnormal blood pressure, hæmorrhage, shock, cahectic conditions, certain organic diseases of the nervous system, and the use of certain drugs, such as atropine, adrenaline, and the nitrites.

Symptoms.—In tachycardia the patient may be conscious of the rapid action of the heart, and occasionally there is præcordial pain. The apex-beat may be diffuse and excited. There may be a systolic murmur at the apex, or base, or both. On the other hand, pre-existing murmurs may disappear.

A polygram and electro-cardiogram show merely an undue decrease of the diastolic interval (see p. 1003), that of the systolic being unaffected.

Diagnosis.—The differential diagnosis between sinus tachycardia and paroxysmal tachycardia is discussed on p. 893.

Treatment.—This resolves itself into dealing with the cause of the condition.

SINUS BRADYCARDIA

By the term bradycardia is meant a decreased cardiac rate. It must be distinguished from infrequency of the pulse-rate at the wrist, since the latter also includes ventricular extra-systole which is so feeble that the wave fails to reach the wrist. There are three varieties of bradycardia: (1) sinus bradycardia; (2) auriculo-ventricular block; and (3) some cases of auriculo-ventricular nodal rhythm. The last is a rare condition. We shall here deal with sinus bradycardia.

Sinus bradycardia is due to a decrease in the function of rhythmicity, the result of increased vagal tone or a direct action on the sino-auricular node. The cardiac rate is below 60 per minute, and is usually between 50 and 60, and rarely is as low as 40 and even less.

Ætiology.—Sinus bradycardia may be physiological, especially in males, advancing age, and athletes. Transient sinus bradycardia may be a physiological reaction to rest, sleep, and pressure on the carotid sinus, especially the right.

The pathological form of bradycardia is less common than is sinus tachycardia. It may occur (1) during the convalescence of acute infective diseases,

especially influenza, diphtheria, pneumonia, typhoid and typhus; (2) in certain toxic conditions, such as jaundice, diabetes and uræmia; (3) in hypothyroidism; (4) in some forms of cardiac disease—especially aortic stenosis and fatty degeneration of the myocardium; (5) in the use of certain drugs, such as digitalis, opium and, exceptionally, tobacco; and (6) during certain diseases of the nervous system.

In a polygram and an electro-cardiogram there is merely an undue prolongation of the diastolic interval (see p. 1003), that of the systolic being unaffected.

Diagnosis.—In sinus bradycardia the rate is only occasionally below 50. It is influenced by physical exertion, emotion, pyrexia, amyl nitrite, and atropine.

Sinus bradycardia should be diagnosed from extra-systoles, 2 : 1 and complete auriculo-ventricular block, and auriculo-ventricular nodal rhythm.

IRREGULAR ACTION OF THE HEART

The subject of irregular action of the heart is of great practical importance. Formerly it was notoriously a source of perplexity and difficulty to the clinician. It was known that irregularity might, on the one hand, signify even serious impairment or disease of the heart, or, on the other, that it might be of no practical consequence. It was not possible, however, to determine the significance of the irregularity in any given case, because there were no means of differentiating the types of irregularity, or what any particular type signified. By means of the electro-cardiograph and the clinical polygraph it is now possible to classify irregular action of the heart into types, and it is known what each type signifies. I would emphasize, however, that the work of elucidation having been accomplished, in a considerable majority of cases the use of a sphygmograph is sufficient, and in a fair proportion palpation and auscultation suffice.

Irregular action of the heart may be due to (1) sinus arrhythmia; (2) extra-systoles, or premature contractions; (3) paroxysmal tachycardia, (4) auriculo-ventricular nodal rhythm; (5) auricular fibrillation; (6) auricular flutter; (7) ventricular fibrillation; (8) heart-block; and (9) the pulsus alternans. The first two varieties are very common.

It may be advisable to describe here what is meant by the terms 'intermittent' pulse or a 'dropped beat,' 'pulsus bigeminus' or 'coupling of the beats,' and 'pulsus trigeminus.'

Intermission of the pulse is a form of irregularity which is not uncommon. By it is meant a condition in which the normal rhythm of the pulse is interrupted, either occasionally or more frequently, either at regular or irregular intervals, by an abnormally long pause during which no wave is felt at the wrist, a beat being missed. It is important to understand how intermission of the pulse is caused, especially from the point of view of prognosis. By far the commonest cause is a premature contraction of the ventricle ('extra-systole') which is so feeble that the wave fails to reach the wrist; the next most common cause is partial heart-block; while the condition is occasionally due to sinus irregularity, and very rarely to sino-auricular block. The differential diagnosis between extra-systole and partial heart-block is discussed under extra-systole. The differential diagnosis also between occasional

dropped beats due on the one hand to sinus irregularity and on the other to partial heart-block is discussed under heart-block.

By *pulsus bigeminus* or *coupling of the beats* is meant a condition in which the pulse-beats occur in pairs, for long or short periods. The paired beats may occur at regular intervals, or at irregular intervals, and some writers restrict the term *pulsus bigeminus* to the former, and that of *coupling of the beats* to the latter. When the paired beats fall at regular intervals, the commonest cause is the occurrence of extra-systoles, usually ventricular, in cases in which the fundamental or sinus rhythm is otherwise maintained;

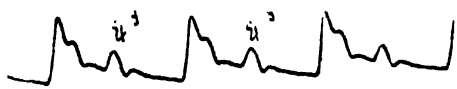

FIG. 24.—Pulsus bigeminus, due to a single extra-systole with its succeeding compensatory pause occurring regularly after each normal beat.

either a single extra-systole with its succeeding compensatory pause occurring regularly after each normal beat (Fig. 24), or such occurring after every two normal beats, the premature contraction in the latter case, however, being so feeble that no waves reaches the wrist. The next most common cause is partial heart-block, when the ventricle fails to respond to every third beat of the auricle (Fig. 25). A rare cause is sino-auricular block, in which the auricle fails to respond to every third impulse generated at the sinus. When the paired beats occur at irregular intervals, the cause is a ventricular extra-systole occurring regularly after each normal ventricular contraction in cases of auricular fibrillation; this is usually due to the action of digitalis (Fig. 31), but may occur independently of it.

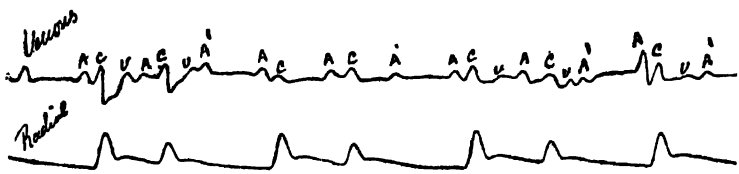

FIG. 25.—Pulsus bigeminus, due to partial heart-block, the ventricle failing to respond to the stimulus from the auricle at *A'*.

By *pulsus trigeminus* is meant a condition in which the pulse-beats are grouped in threes. The causes are: (1) extra-systoles—either a single extra-systole with its succeeding compensatory pause after every two normal beats, or such after every three normal beats and failing to send a wave to the wrist; (2) partial heart-block, when the ventricle fails to respond to every fourth beat of the auricle; and, rarely (3), sino-auricular block, in which the auricle fails to respond to every fourth impulse generated at the sinus.

The differential diagnosis between intermission of the pulse, pulsus bigeminus, and pulsus trigeminus due to the various causes mentioned is discussed elsewhere.

SINUS ARRHYTHMIA

This is a normal phenomenon, which is very frequent, both in health and disease. It is due to variation of vagal tone acting upon the sino-auricular node.

The chief characteristics of sinus irregularity is the variation in the length of the diastolic interval, the systolic being unaffected. The irregularity may be slight or even marked. In the great majority of cases it is related to respiration, the cardiac rate gradually increasing during inspiration and gradually diminishing during expiration. If not related to respiration, the irregularity may be only present during slow deep breathing. There is an abrupt slowing of a few beats and then a gradual increase.

Ætiology.—Sinus arrhythmia is much more frequent during childhood and adolescence, but may be found at all ages. It sometimes occurs after a febrile illness, and occasionally during the administration of digitalis, and even the act of swallowing may produce it—the heart-rate during the act being quickened for a few beats, followed by a reduction in the rate.

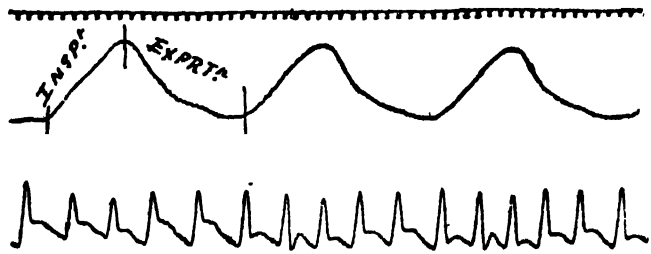

Fig. 26.—Simultaneous tracings of the respiration and the radial pulse, from a healthy boy aged 14, showing sinus irregularity.

Symptoms.—Usually there are no subjective symptoms, but rarely those of cerebral anæmia, such as giddiness, or faintness or even actual syncope, occur during an unusually long pause. On auscultation, the interval between the first and second sounds is found to be constant, while the varying length of the diastolic interval can be detected. If a tracing of the radial artery be taken, the intervals between the beats will be found to vary, while the pulse-beats are of equal or nearly equal size (Fig. 26). A polygram and an electrocardiogram (Figs. 58–60) show merely either of the two variations in the length of the diastolic periods just described.

The irregularity is diminished or abolished by an increase in the cardiac rate.

Diagnosis.—A diagnosis may be made from the features described. When irregularity of the cardiac action is found to be definitely related to respiration, it is in all probability of the sinus type.

Prognosis.—There is no reason to suppose that sinus irregularity is either indicative of an impaired heart, or that it adds to the gravity of any diseased cardiac condition which may be present. The condition, therefore, may be entirely disregarded.

Treatment.—No treatment is required.

THE EXTRA-SYSTOLE

Synonym.—Premature Contraction.

By extra-systole is meant a premature contraction the result of an impulse which is generated at some site other than the sino-auricular node.

It has been noted that if rhythmicity is more developed at any other portion of the primitive cardiac tube than the sinus, the impulse arises at that point (see p. 847).

There are three varieties of extra-systoles, according to whether the point of origin is situated in the auricle, or the auriculo-ventricular node or bundle above its division, or the ventricle. The first is called auricular extra-systole; the second, auriculo-ventricular nodal extra-systole; and the third, ventricular extra-systole.

In each case the sinus rhythm is otherwise maintained in most cases. Usually an extra-systole is followed by a long pause (compensatory pause). Rarely the premature contraction occurs between two normal beats (interpolated extra-systole).

Of the three varieties of extra-systoles, the ventricular is far the most

FIG. 27.—Simultaneous tracings of the jugular and radial pulses, showing a ventricular extra-systole at *Ex.s.* The usual rhythm of the auricle is maintained. The extra-systole in the jugular tracing is represented by the wave *c'*, immediately before the systole of the auricle. The compensatory pause is complete.

common, and the auricular the next frequent. The variety of extra-systoles in the same individual is usually constant, but the three varieties may occur in the same subject. Occasionally premature contractions arising from different foci are observed in one record—multiple extra-systoles.

Extra-systoles may occur at long intervals, or at frequent, irregular intervals; or regularly after each beat, or after every second, or third, or more, normal beats; or there may be a rapid succession of extra-systoles—usually persisting for a few cycles only (Fig. 62), but rarely even for a few minutes.

THE VENTRICULAR VARIETY OF EXTRA-SYSTOLE.—We may take this variety for the purpose of illustration. While the chambers of the heart are contracting in the normal fashion, a premature contraction of the ventricle takes place, this arising independently of a stimulus from the auricle, which maintains its usual rhythm and contracts as the result of the normal stimulus from the sinus. The exact time at which the premature contraction of the ventricle takes place is either immediately before the systole of the auricle (Fig. 27), or—as is usually the case—synchronously with it, or

after it, but prior to that point of time at which it would have occurred if this had been in response to a stimulus received from the auricle in the normal way. In most cases the succeeding impulse from the auricle fails to cause a contraction of the ventricle; for this reason the pause which follows the premature contraction is abnormally long, being called the *compensatory pause*. When this prolonged diastole and the preceding shortened diastole together equal in time two normal cardiac cycles, the compensatory pause is said to be *complete*. Since during the prolonged pause the ventricle has had an unusually long period in which to fill and recuperate, the pulse-beat immediately following a compensatory pause has often a greater amplitude than on other occasions. Sometimes, more especially when the cardiac rate is slow, a ventricular extra-systole occurs so early in the cardiac cycle that the ventricle does contract in response to the normal stimulus which is transmitted from the auricle immediately after the premature contraction; in this way a premature contraction is interpolated between two normal beats. This form of the extra-systole is called *interpolated* (Fig. 28).

On auscultation, in the vast majority of cases, two heart-sounds are

FIG. 28.—Simultaneous tracings of the jugular and radial pulses, showing an interpolated ventricular extra-systole (c' and r'), represented in the diagram by the downstroke +. The downstrokes in the space *As* represent the auricular waves (a) in the jugular, and the downstrokes in the space *Vs* represent the carotid waves c, and the slanting lines connecting them represent the a–c interval (Mackenzie).

synchronous with each extra-systole, these forming with those of the preceding normal contraction a group of four sounds. Sometimes, however, the extra-systole occurs early in diastole, and before the cardiac muscle has had sufficient time to recover fully from the preceding systole, in which event the premature contraction is so feeble as to fail to open the aortic valves, and only the first sound is heard; in this way a group of three sounds becomes audible. Very rarely the premature contraction is so feeble as not to produce any cardiac sounds whatever.

The amplitude of the pulse-wave of an extra-systole is not so great as that of a contraction occurring at a normal interval, because the heart muscle has not had time to recover from its previous effort. The earlier an extra-systole occurs in the diastole, the more feeble it is; it may be so feeble that no wave is felt at the wrist, so that there is simply an abnormally long pause, resulting in what is called a "dropped beat" or an "intermittent" pulse; as has been already noted, an extra-systole which fails to reach the wrist is, indeed, the most usual cause of an intermittent pulse. If a single extra-systole with its succeeding compensatory pause occurs regularly after each normal beat, then the beats at the cardiac apex occur in pairs, as also do the pulse-beats, the condition being called *pulsus bigeminus* (Fig. 24). Simi-

larly, if a single extra-systole with its succeeding compensatory pause occurs after every two normal beats, then the apex-beat occurs in threes, as also do the pulse-beats, the condition being known as *pulsus trigeminus*; but if the premature contraction is so feeble that no wave reaches the wrist, the pulse-beats are paired.

If a polygraphic record of a case of ventricular extra-systole (Fig. 27) be analysed, it will be found that, as the normal rhythm proceeds as usual, the *a* wave appears at regular intervals; each *a* wave is followed by a *c* wave, except when an extra-systole occurs, when the *c* wave either precedes the *a* wave, or—as is more commonly the case—occurs synchronously with it, in which case the amplitude of the wave is correspondingly increased.

Auricular Variety of Extra-Systole.—In this variety there is a premature contraction of the auricle, the stimulus arising in the wall of the auricle prior to the normal stimulus from the sinus. The premature contraction of the auricle is usually followed by a premature contraction of the ventricle, following the usual transmission of the stimulus from the auricle along the auriculo-ventricular bundle. Not infrequently, in the case of extra-systole the stimulus from auricle to ventricle travels slowly, so that the *As–Vs* interval is lengthened, and the prematurity of the ventricular systole is consequently not so great as that of the auricle; in this way the compensatory pause is shortened. In some instances the contraction which immediately follows the extra-systole takes place rather earlier than the normal interval, this being probably due to the unusual length of the rest period; in this way there is further encroachment upon the compensatory pause. This is less marked in the case of the second contraction, and it disappears within a few cycles. Sometimes there are variations in the rate of transmission of these auricular premature contractions to the ventricle.

Occasionally the stimulus from the auricle does not reach the ventricle at all, and no premature contraction of this chamber takes place, in which event the premature contraction of the auricle is not followed by a premature contraction of the ventricle, the condition being known as 'blocked auricular extra-systoles (Fig. 63). In these cases a long pause is to be noted in the sphygmogram. As in the case of the ventricular variety, an auricular extra-systole is followed by a lengthened pause; but, with rare exceptions, this compensatory pause is not complete. In some cases, however, the compensatory pause is complete.

In a polygraphic record of a case of auricular extra-systole, each *c* wave is preceded by an *a* wave, while there is a premature *a* wave and a premature *c* wave, sometimes with an increased *a–c* interval, and an alteration of the relative position of the beats following the extra-systole.

Auriculo-Ventricular Nodal Variety of Extra-Systole.—In this variety the stimulus for premature contraction originates in the auriculo-ventricular node or bundle above its division, travelling upwards into the auricle and downwards into the ventricle, and giving rise to a premature and simultaneous contraction of both auricle and ventricle. The premature ventricular contraction more or less coincides with that of the auricle, but this is by no means absolute; the contraction of both chambers may be absolutely synchronous, or the ventricular systole may begin after or before that of the auricle. When the auricular contraction occurs before that of the ventricle, the period of time between the contraction of the upper and

lower chambers is shortened. The compensatory pause may or may not be complete.

In a tracing of the jugular vein from a case of auriculo-ventricular nodal extra-systole, there is prematurity of the *a* wave, and also of the *c* wave; when the premature contraction of the chambers is synchronous, both waves are combined, in which case the amplitude of the wave is increased; when the auricular contraction occurs before that of the ventricle, the *a* wave precedes the *c* wave, but the *a–c* interval is diminished to about 0·10 sec.

In the ventricular and auriculo-ventricular nodal varieties of extra-systoles, in contrast with the 'double' venous pulsation in the jugular vein which may be visible in the case of the auricular variety, there is usually an unduly large 'single' pulsation coincident with the premature contraction; this is due to the contraction of the upper and lower chambers of the heart occurring synchronously, the result being that the auricle, instead of discharging its contents into the ventricle, does so into the venæ cavæ.

Ætiology and Pathology.—Extra-systoles may be met with at any age, but are much more frequent in the elderly and middle-aged, especially the former, than in the young, and are rare during the first decade of life, and are more common in men than in women. They are more frequent in the subjects of organic disease of the heart than in those who are not, and in myocardial than in valvular affections. They are to be found in digestive disturbances, especially when attended with flatulent distension, acute infections, hypertension, arterial disease, focal sepsis, thyrotoxicosis, the excessive consumption of tea, coffee, tobacco and alcohol, emotional states, and as the result of the administration of certain drugs, such as digitalis, barium, aconite and chloroform. In a considerable proportion of cases there is no ascertainable cause. Extra-systoles are especially apt to occur during rest following physical exertion, soon after getting into bed, change of posture, after a big meal and during cardiac dilatation with failure.

Extra-systoles indicate that at the time of the premature contraction some portion of the myocardium below the sinus is more excitable than the sinus. This may or may not be due to some structural change in the myocardium; it may, for example, be caused by poisoning of the heart wall without structural damage.

Subjective Symptoms.—An individual in whom extra-systoles occur may be unconscious of their presence. On the other hand, he may experience a sensation of fluttering in the chest when a premature beat occurs: or he may be conscious of the long pause and complain of intermission of the pulse, or that the 'heart stops'; or the contraction of the heart following the pause may be accompanied by the consciousness of a thud or shock in the region of the heart, sometimes followed by a feeling of exhaustion. The patient may complain of a sensation of a 'catch in the breath,' or of 'gripping in the throat.' Very rarely, during a prolonged pause, giddiness, faintness, or even actual syncope may take place.

Diagnosis.—Extra-systoles may be recognised with certainty by means of the electro-cardiograph or the clinical polygraph. But it is important to recognise that in the majority of cases a correct diagnosis can be made simply by palpation and auscultation. The normal rhythm of the heart is disturbed by the occurrence of a premature beat in the radial pulse and at the cardiac apex, followed by an abnormally long pause. The auscultatory signs have

already been noted; they are of much diagnostic value. When, on palpation of the radial artery, an apparently otherwise regular pulse is sometimes interrupted by an unusually long pause, it should suggest either an extra-systole which is so feeble that no wave is felt at the wrist, or partial heart-block. When the former is responsible, a premature beat can be detected at the cardiac apex and on auscultation one or two heart-sounds will, in the great majority of cases, be audible during the early part of the pause, because the ventricle has contracted; whereas in the case of partial heart-block there will be absence of an apex-thrust and of heart-sounds during the pause, because the ventricle has failed to contract. Further, in the case of extra-systole, a wave is usually present in a sphygmographic tracing, and a premature contraction is always visible in a tracing of the apex-beat. These three features are almost invariably sufficient to distinguish between an intermittent pulse due to an extra-systole which fails to reach the wrist and that due to partial heart-block. An electro-cardiogram or a polygram will place the matter beyond doubt. It may be here noted that it is necessary to exclude sinus irregularity and also sino-auricular block, in cases of an unusually long pause in the radial pulse. The differential diagnosis between pulsus bigeminus, pulsus trigeminus, and infrequency, including halving, of the pulse rate, due on the one hand to extra-systoles, and on the other to partial heart-block, can also readily be made, as a rule, by means of palpation and auscultation.

It is sometimes very difficult, if not impossible, by palpation and auscultation alone, to diagnose extra-systoles, occurring frequently and at irregular intervals, especially if of auricular origin, from auricular fibrillation. Extra-systoles are diminished or abolished by an increase in the cardiac rate, while the opposite obtains in auricular fibrillation. Again, a sphygmographic tracing is almost invariably sufficient. It is also necessary to exclude auricular flutter when the response of the ventricle to auricular contraction is at irregular intervals (p. 902, and Fig. 76).

Prognosis.—The question of prognosis of extra-systoles is of some consequence. Unfortunately the lay mind has come to attach an unnecessary significance to them. Furthermore, the medical practitioner should understand that extra-systoles constitute one of the most frequent causes of irregularity of the pulse, and that an extra-systole which fails to reach the wrist is the commonest cause of an 'intermittent' pulse. Apart from rare exceptions (see below), when extra-systoles are considered by themselves—that is, without reference to the conditions with which they may be associated—there is so far no evidence for supposing that they are either indicative of an impaired heart, or that they add to the gravity of any existing morbid condition. While it is true that extra-systoles may precede the occurrence of other forms of cardiac irregularity, such as the complete irregularity associated with auricular fibrillation, it should be borne in mind that these might have arisen independently. The prognosis, therefore, should be based entirely upon the causal or associated condition.

The significance of a rapid succession of extra-systoles has some relation to that of paroxysmal tachycardia. Multiple extra-systoles of ventricular origin are usually of very serious significance, and are generally a presage of ventricular fibrillation.

Treatment.—Our first duty is to reassure the patient; this may be done

with confidence. The ætiology of extra-systole should be thoroughly reviewed, the general health should receive attention, and if cardiac failure be present it should be treated on the lines laid down elsewhere. Some writers speak well of quinidine, 5 to 15 grains per diem, for the irregularity itself, but this does not accord with my experience. Neither have I found digitalis of any value. Sedatives (see p. 863) are frequently of benefit for the associated symptoms, especially when there is irritability of the nervous system or insomnia.

PAROXYSMAL TACHYCARDIA

By the term paroxysmal tachycardia is meant a condition in which a marked acceleration of the cardiac rate occurs, which commences abruptly and usually without apparent cause, lasts for a varying period, ceases abruptly, and is due to an abnormal rhythm, the stimulus for contraction arising at some site other than the sino-auricular node. The return of the cardiac rate to what it was prior to the paroxysm is due to the reversion of the cardiac rhythm to the normal.

It is necessary to point out that under this term some writers include paroxysmal auricular flutter with marked acceleration of the ventricular rate, and paroxysmal auricular fibrillation with marked acceleration of the ventricular rate, using the term " simple " paroxysmal tachycardia for the other cases. I shall not include these two conditions.

The first beat of the paroxysm is premature, and usually the paroxysm is followed by a long pause, as in the case of extra-systole, before the normal rhythm is restored. The individual beats of the paroxysm are essentially the same as those of isolated extra-systoles. Between the attacks there may be single extra-systoles. The site of origin of these is usually the same as of the beats of the paroxysm.

There are three varieties of paroxysmal tachycardia, according to whether the point of origin of the new rhythm is situated in the auricle, the auriculo-ventricular node, or the ventricle—in that order of frequency. The first is called auricular paroxysmal tachycardia ; the second, auriculo-ventricular nodal paroxysmal tachycardia ; and the third, ventricular tachycardia. The first two varieties together constitute supraventricular paroxysmal tachycardia. In the auriculo-ventricular nodal variety there is a simultaneous contraction of both auricle and ventricle ; the contraction of both chambers may be absolutely synchronous, or the ventricular systole may begin after, or before, that of the auricle. The variety of the paroxysms in the same individual is almost invariably constant.

The paroxysms may last only for a few beats, or up to a few days, or, rarely, even a few weeks or more. The patient may experience one attack and never have another ; or he may have many in the course of 24 hours ; or the attacks may occur at varying intervals, frequent or long, for many years.

Ætiology.—The ætiology of paroxysmal tachycardia is obscure. The malady may occur at any age, but usually is first met with during middle life, and appears to be more common in males. A history of previous infection by rheumatism is not infrequent, and a fair proportion of cases are the subjects of chronic valvular disease, particularly mitral stenosis, or of myo-

cardial disease. Paroxysmal tachycardia is occasionally met with in coronary occlusion, when it is most likely to be of the ventricular type, focal sepsis, thyrotoxicosis, and the excessive use of tea, coffee, tobacco or alcohol.

Usually there is no exciting cause of the attacks, but among such are physical exertion, emotional excitement, digestive disorders, especially with flatulent distension, and very rarely the adoption of a certain posture.

The ventricular variety is most frequently met with in later life, and in the vast majority of cases is associated with serious organic disease of the heart, especially coronary occlusion, and very rarely in fatal cases of digitalis poisoning.

Symptoms.—In some cases the patient is able to recognise both the onset and termination of the attack. If the attack be brief, he may be unconscious of the tachycardia. If it persists for a time, however, he is usually conscious of it, and generally complains of rapid action of the heart, or of a fluttering sensation in the chest, or palpitation; and occasionally of throbbing or pulsation in the neck, the head, or some other part of the body. The face is generally pale and has an anxious expression. The patient may complain of a sense of exhaustion, and of oppression or discomfort or even pain in the chest. There may be abdominal distension, or nausea, or vomiting. Quickened or even distressed breathing may be present. There may be giddiness, faintness, or even loss of consciousness, and rarely convulsions. The usual symptoms of cardiac failure, commonly both left- and right-sided, generally supervene; or, if these were present before the attack, they increase in severity. The degree of failure depends upon the cardiac rate, the duration of the paroxysm, its variety, any associated morbid condition, and the integrity of the myocardium. In long-continued paroxysms, and even in some cases in which they last for only a few hours, it may be severe or even extreme. It is usually more severe in the ventricular variety. In a small proportion of cases, anginal pain occurs.

The cardiac rate may range from 120 to 250. In the majority of cases it is between 160 and 200, being usually more rapid in the ventricular variety. The effect of posture, physical exertion and pressure on the carotid sinus on the pulse-rate is described under Diagnosis. The pulse is of smaller volume than normal. Not infrequently the pulsus alternans is present. In the auriculo-ventricular nodal and the ventricular varieties, the rhythm may be irregular, but the irregularity is so slight that it is detected only by graphic methods. The blood pressure is generally lowered during an attack. The cardiac sounds may be shorter and sharper and feeble. If murmurs were present prior to the onset of the attack, they may become faint or even disappear; this applies particularly in the case of a mitral presystolic bruit. The jugular veins may be distended, and there may be the ventricular form of the jugular pulse. The results of X-ray examination show that the heart often becomes actually smaller during short attacks, but in cases in which the attacks are of long duration or the organ is seriously diseased, considerable and rapid—often within a few hours—cardiac dilatation may occur, in which case the physical signs thereof, described on p. 956, may be noted.

Analysis of polygraphic tracings gives different results according to the nature of the abnormal rhythm.

A remarkable feature of the condition is that with the sudden reversion of the rhythm to normal there is usually an extraordinarily rapid recovery to

the state in which the patient was prior to the paroxysm. In some cases the cessation of the attack is accompanied by the passage of large quantities of wind and excessive eructations, while a large quantity of urine may be voided.

Diagnosis.—We should think of the possibility of paroxysmal tachycardia (or of auricular flutter), whenever an individual complains of attacks of palpitation, or is conscious of a marked increase in the cardiac rate, in either case occurring suddenly and without apparent cause, or suffers from indications of cardiac failure coming on rapidly, if the rhythm of the pulse be regular.

Paroxysmal tachycardia should be distinguished from sinus tachycardia, and auricular flutter with continuous 2 : 1 auriculo-ventricular block.

The most important factors in the diagnosis of the condition are: (1) Usually there is no exciting cause of the paroxysm, unlike sinus tachycardia. (2) The commencement and termination of the attack of tachycardia are sudden—the maximum rate is attained within a few beats, and the return of the cardiac rate to what it was prior to the attack or, as in some cases, to near this, occurs equally suddenly; whereas in tachycardia associated with the normal rhythm the onset and termination are gradual. (3) A persistent rate of over 160 is almost always due to an abnormal rhythm, and of over 140 usually so. If the rhythm is regular, the condition is either paroxysmal tachycardia, or 2 : 1 auricular flutter; while if completely irregular, auricular fibrillation. (4) In normal rhythm the cardiac rate is influenced by posture, physical exertion and pressure on the carotid sinus, especially the right. In paroxysmal tachycardia the rate is not affected by these—excepting that carotid pressure may cause the paroxysm to cease. In all cases electrocardiographic examination will put the diagnosis beyond doubt (see pp. 1012–1014).

The differential diagnosis between paroxysmal tachycardia and 2 : 1 auricular flutter is discussed on p. 902.

For the differential diagnosis of the varieties of paroxysmal tachycardia, see pp. 1012–1014.

Prognosis.—The prognosis in any case of paroxysmal tachycardia is difficult. It may be considered from two points of view: (1) That of a particular paroxysm; and (2) the question of recurrence of the attacks.

With regard to the former, the points which should be taken into account are the nature and degree of any associated morbid condition, the variety of the paroxysm, the ventricular rate, the duration of the attack, the integrity of the myocardium, and the history of any previous attacks. In the vast majority of cases the ventricular variety is associated with serious organic disease. The question of cardio-vascular organic disease is of much greater moment than the cardiac rate. When the ventricular rate is not very high, and there is an absence of œdema of the lungs, hepatic enlargement and systemic œdema, and there is little or no cardiac dilatation, the outlook is good as far as the risk to life is concerned; while, on the other hand, if the clinical picture is the reverse, it is uncertain—but it should be remembered that the paroxysm may cease at any time, in which event the patient may improve with surprising rapidity. Death during an attack is of rare occurrence, although it may happen, especially if the tachycardia is of ventricular origin.

With regard to the question of the recurrence of the attacks, it is impossible to give an answer. The patient may never suffer from a subsequent attack; while, on the other hand, they may recur even several times in the course of 24 hours, or at frequent intervals for many years. There is, however, a tendency to a recurrence.

Treatment.—This resolves itself into two parts: (1) Treatment during an attack; and (2) the prevention, if possible, of the recurrence of the attacks.

With regard to the first of these, the results of treatment are in the majority of cases unsatisfactory. It is true that the paroxysm not infrequently ceases when various remedies are applied, but it should be remembered that the nature of the disorder is to stop suddenly and, therefore, the question of *post hoc* and *propter hoc* arises.

The patient should rest, either in the recumbent position or sitting in an easy-chair, and keep as quiet as possible.

The following methods of treatment may be tried in the auricular and nodal varieties: The adoption of certain postures, such as bending the body, with, it may be, the head between the knees; various movements of the body; rapid deep breathing; holding the breath as long as possible, including after a deep inspiration or a deep expiration; local applications, such as hot fomentations, or poultices, an ice-bag, or a mustard-leaf, to the præcordium; firm compression to the abdomen; a carminative, or a diffusible stimulant, or drinking ice-cold water; the induction of vomiting; moderately firm pressure on either eyeball, with the eye closed; and firm pressure with the tips of the fingers on the carotid sinus in the right or left side of the neck for a quarter to a half minute or more, stopping short of pain, repeated several times if necessary. The last is the most likely to be successful. Failing these measures, a stiff dose of bromide and chloral, without or with opium, by the mouth. Morphine ($\frac{1}{2}$ grain suppository, or $\frac{1}{4}$ grain hypodermically), provided there is an absence of a reasonable fear of the patient becoming an addict to the drug. Quinidine may be tried, if the patient can be assiduously watched and there is an absence of idiosyncrasy to the drug (see p. 871). Six grains may be given every two or three hours for four or five doses. Recently the drug has been administered intravenously, but this is not recommended. If the foregoing measures are unsuccessful, massive doses of digitalis by the mouth, or digoxin or strophanthin intravenously, are rarely effective.

In the ventricular variety, quinidine may be tried. Massive dosage of digitalis is even contra-indicated.

Respecting the prevention of the recurrence of the attacks, a searching inquiry should be made for both the underlying and exciting causes, with the object of treating them. Sedatives (see p. 863) are often used. Quinidine, 5 to 15 grains per diem, is not infrequently successful. Digitalis, in moderate dosage, is occasionally so.

AURICULO-VENTRICULAR NODAL RHYTHM

This is a rare condition, in which the impulse is generated in the auriculo-ventricular node, and travels upwards into the auricles and downwards into the ventricles, giving rise to a simultaneous contraction of both auricles and

ventricles. There is generally depression of the function of rhythmicity at the sino-auricular node due to the action of the vagus.

The condition is believed to occur more often in the young, and may be met with in digitalis and acute infections. The new rhythm is usually temporary, and generally recurs. It may last for a few beats up to a few days or even longer. It is frequently abolished by physical exertion and atropine. If only an isolated beat is involved, there is a ' nodal escape.'

The rate varies between 30 and 50 and rarely more, being usually about 40. In some cases a large pulsation in the jugular vein, the result of the simultaneous contraction of the auricles and ventricles, is to be observed.

The contraction of the upper and lower chambers may be absolutely synchronous, or the ventricular systole may begin after, or before, that of the auricle, the last being the most common. In the first instance, the *a* and *c* waves of a polygraphic tracing are superimposed, in which case the amplitude of the *a* wave is increased; while in the second, the *a* wave precedes the *c* wave, but the *a*–*c* interval is diminished to about 0·10 sec.

Auriculo-ventricular nodal rhythm should be diagnosed from auriculo-ventricular block and sinus bradycardia.

The condition is of no clinical importance.

AURICULAR FIBRILLATION

It is of great practical importance that auricular fibrillation should be recognised, owing to its bearing on the diagnosis, prognosis and treatment of cardiac affections. It is a specific clinical condition, which can be recognised with certainty. It is characterized by an absence of all signs of the normal contraction of the auricles, and in the vast majority of cases by complete irregularity of the arterial pulse. It accounts for approximately 50 per cent. of all cases of persistent irregularity of the heart, and it is found in from 60 to 70 per cent. of all cases of serious cardiac failure with dropsy. The condition has been known variously as ' delirium cordis,' ' pulsus irregularis perpetuus,' and the ' mitral ' pulse.

By auricular fibrillation is meant a condition in which co-ordinate contraction in the auricle is replaced by inco-ordinate contraction, the individual fibres, or groups of fibres, instead of contracting in an orderly and simultaneous manner, doing so rapidly and independently of each other, with the result that systole of the chamber as a whole never takes place. When auricular fibrillation has once set in, in the great majority of cases it is permanent. But, instead of this, it may be paroxysmal (Fig. 29). The tendency to occurrence increases, however, until finally the condition usually becomes persistent or established.

Effect of Auricular Fibrillation on the Heart.—The effect of auricular fibrillation on the cardiac action is mainly threefold: (1) The forcible contraction of the auricles driving the blood through the open auriculo-ventricular valves into the ventricles during the latter part of ventricular diastole is lost. This results in the ventricle being less filled. (2) Instead of the ventricle receiving impulses from the auricle at regular intervals, it receives them at completely irregular intervals. (3) In the great majority of cases there is an increase in the ventricular rate. The result of these three factors combined is that some of the ventricular contractions are

so feeble as to fail to open the aortic valves, and the pulse is diminished in volume and its rhythm is irregularly irregular. The third factor is the most important.

Ætiology.—The majority of cases of auricular fibrillation fall within two groups, especially the first: (1) those with a history of rheumatism; and (2) patients suffering from chronic myocardial disease, coronary disease, or hypertension. In the case of the former, the condition occurs more commonly in early middle age and in females, and the patients frequently have chronic valvular disease, much more often mitral, especially stenosis, than aortic, in which it is comparatively rare. In the second group of cases, it is more common in the elderly and in males. The next most frequent cause is thyrotoxic conditions (see pp. 486, 491, and 996), and the next is syphilis. Auricular fibrillation has been also found occasionally in acute infective diseases, such as pneumonia, infective endocarditis, and diphtheria, in coronary occlusion, and in the terminal stages of various exhausting diseases. Occasionally there is no apparent cause.

The onset of the disorder can now and again be traced to bodily effort,

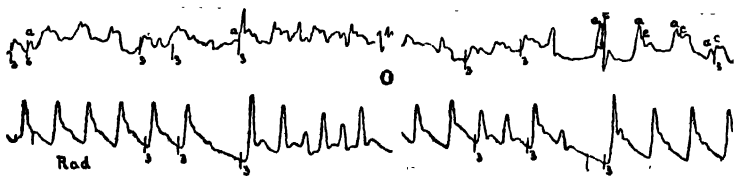

FIG. 29.—Simultaneous tracings of the jugular and radial pulses, showing the commencement and termination of a short attack of paroxysmal auricular fibrillation. The first six beats and the last three in the sphygmogram are regular and due to a normal contraction of the heart. The beats between occur during a period of auricular fibrillation. At *O* a period of 15 seconds has been cut out. (Mackenzie.)

especially in the middle-aged or elderly, perhaps to trauma, and rarely to the administration of fatal doses of digitalis.

Pathology.—Auricular fibrillation is, in the majority of cases, indicative of some myocardial change, usually fibrosis.

It was observed by Mackenzie that, in cases of complete irregularity of the pulse, the pre-existing auricular wave in the phlebogram had disappeared. From this he inferred first, that the auricles were paralysed and, later, instead of this, that auriculo-ventricular nodal rhythm was present. Some time afterwards, Rothberger and Winterberg, and Lewis attributed the absence of auricular contractions to auricular fibrillation, a condition which had been produced experimentally in animals.

The exact mechanism of auricular fibrillation and auricular flutter has been further elucidated by Lewis and his co-workers, and it is now generally but not universally accepted that a *circus movement* is responsible. Mines and Garrey had demonstrated that in a circular ring of muscle, under certain conditions, a wave of contraction can be made to circulate continuously. This is only possible if the crest of the circulating wave encounters muscle which is responsive, *i.e.* which has recovered from the refractory state that immediately follows contraction. Thus, the refractory period at a given point

on the circuit must be less than the time taken by the wave to make a full circuit. If we consider a wave of contraction circulating in such a simple muscular ring, at any given moment, the crest of the wave has in its wake a zone of muscle which is refractory, and between the tail of the refractory zone and the crest of the wave is a zone of muscle which is responsive, known as the gap. The length of this gap is influenced by three factors, namely: (1) The length of the circular path; (2) the rate at which the wave circulates; and (3) the refractory period of the muscle. Lengthening of the path, slowing of the conduction rate, and shortening of the refractory period tend to increase the gap; while shortening of the path, increase of the conduction rate, and lengthening of the refractory period tend to decrease or abolish the gap.

It has been shown that in both auricular fibrillation and auricular flutter a circus movement is present in the auricles, which no longer respond to the regular stimuli from the sino-auricular node. In auricular flutter the pathway of the main circulating wave probably encircles the orifices of the two venæ cavæ. The wave circulates at a rate of 180 to 360 per minute, and constantly traverses the same path. In auricular fibrillation the circulating wave is faster, being between 300 and 600 per minute, and the path is shorter,

FIG. 30.—Tracing of the radial pulse, from a case of auricular fibrillation, showing complete irregularity of the pulse.

more sinuous and variable. The gap is very short, so that the crest and the wake of the circulating wave are almost fused, and the crest is advancing through irregular channels. In both flutter and fibrillation the auricular muscle is responding to stimuli from a central circulating wave, from which offshoots or subsidiary waves pass in all directions towards the periphery. Intermediate between pure flutter and fibrillation is a condition termed impure flutter, in which the rate of the circulating wave is 350 to 400, and the path traversed is not absolutely constant, as in the case of pure flutter.

Prolongation of the refractory period in auricular fibrillation and in auricular flutter will help to close the gap between the crest of the oncoming wave and its receding wake, since this gap is necessary for the maintenance of the circulating wave, whether in flutter or fibrillation.

Symptoms.—Patients with auricular fibrillation frequently complain of a sensation of fluttering in the præcordium, or of irregular action of the heart, or of both, possibly only on exertion. Apart from this, occasionally there is an absence of subjective symptoms. In the great majority of cases, however, ever, symptoms of heart failure, generally involving both ventricles, are present. It would appear, however, that paroxysmal dyspnœa and acute pulmonary œdema rarely if ever occur. The subjects of auricular fibrillation also rarely suffer from typical attacks of angina pectoris. Embolism is occasionally met with.

The degree of failure may vary from slight to even extreme. As a rule, the onset of symptoms is gradual, but may ensue rapidly, and the patient may become very ill within a few weeks, or days, or, rarely, even a few hours. Both depend upon the ventricular rate, the cause and any associated morbid condition, and the integrity of the myocardium, perhaps chiefly the first.

There is a wide variation in the ventricular rate, according as the pathway for impulses to the ventricle is free or interfered with, this ranging from 140 or even 180 to 40, or, very rarely, even 30 per minute in complete auri-

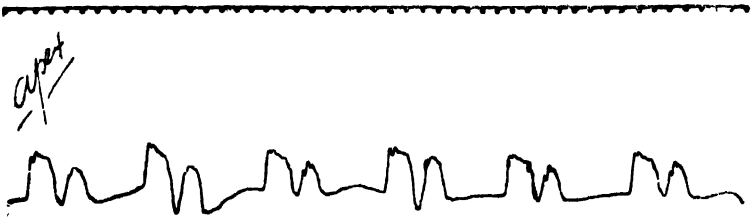

Fig. 31.—Tracing of the apex-beat, from a case of auricular fibrillation, fully under the influence of digitalis, showing coupled beats.

culo-ventricular heart-block. In the great majority of cases the rate is increased, being usually between 90 and 140. The rate of the radial pulse does not necessarily represent the ventricular rate, for many beats of the heart may not be transmitted to the wrist, especially, when the ventricle is beating rapidly; the ventricular rate, therefore, should be counted at the apex, by auscultation. Apart from the very rare cases of complete auriculo-ventricular block, in which case the pulse is regular, the pulse is completely irregular. In a sphygmogram (Fig. 30) it will be found that two

Fig. 32.—Simultaneous tracings of the jugular and radial pulses, from a case of auricular fibrillation, showing multiple undulations (marked Fibl.) in the phlebogram, caused by the fibrillating auricle.

beats of the same length or amplitude rarely follow each other. There is often no relation also between the length of a pause and the amplitude of the beat which follows it—*i.e.* a short pause may be followed by a strong beat, and a long pause by a weak beat. There may be superadded ventricular extra-systoles. Their presence is usually observed during the administration of one of the digitalis group of drugs (see page 868). When the ventricular rate is slow, or very rapid, the irregularity may be only slight, and we may have to adopt careful measurements of the sphygmogram to detect it. In cases of mitral stenosis in which a presystolic bruit, *due to auricular systole,*

is present, this disappears with the onset of auricular fibrillation; while if a diastolic bruit be present, it persists.

The jugular veins may be so distended that there is no visible pulsation in them. When pulsation is visible, however, it is of the positive type, only one wave being visible, this occurring during ventricular systole. In a tracing of the jugular vein, apart from the very rare cases of complete auriculo-ventricular block, when the rhythm is regular, the rhythm is completely irregular. There is an absence of the *a* wave. There may be the ventricular form of venous pulse. In cases in which there is infrequent cardiac action, multiple undulations, caused by the fibrillating auricle, may be present during diastole. There is also an absence of the normal *a* wave in a cardiogram and in a tracing of the liver pulse.

Diagnosis.—Auricular fibrillation can be diagnosed with certainty on electro-cardiographic examination; or when complete irregularity of the arterial pulse, the ventricular form of venous pulse, and multiple undulations in the jugular pulse are present, together with an absence of all signs of an auricular wave in a tracing of the apex-beat and of the liver pulse; or when there is complete irregularity of the pulse in conjunction with the ventricular form of venous pulse; the first being the most reliable. We may be reasonably certain from the mere presence of complete irregularity of the pulse. It is possible to determine complete irregularity of the pulse in a large proportion of cases by palpation and auscultation alone. When, however, the ventricular rate is slow, or very rapid, it may be necessary to adopt careful measurements of a sphygmogram to detect it.

Auricular fibrillation should be distinguished from sinus arrhythmia (p. 885), extra-systole (p. 889), and auricular flutter (p. 902).

Prognosis.—Auricular fibrillation is in the majority of cases indicative of some myocardial change. Furthermore, the condition usually has a considerable effect on the cardiac efficiency. Put briefly, the prognosis depends upon the ventricular rate, the cause, the nature and degree of any associated morbid condition, the integrity of the myocardium, and the response to the administration of the digitalis group of drugs, or, less frequently, to quinidine. If there is an absence of tachycardia, or the tachycardia is only of moderate grade or of more severe grade, but well controlled by digitalis, and if the integrity of the myocardium be relatively good, the patient may live even for many years. In the great majority of cases this is not the case. A persistent ventricular rate of 120 or over is usually of serious omen. Occasionally, with the inception of auricular fibrillation, grave cardiac failure may supervene with surprising rapidity, and death may follow within a few weeks, or even within a briefer period.

As has been pointed out, paroxysmal auricular fibrillation has a tendency to become more frequent, and ultimately the condition usually becomes permanent.

Auricular fibrillation associated with thyrotoxicosis is dealt with on p. 997.

Treatment.—The ætiology should be reviewed, with the object of treating any associated condition, and the various therapeutic measures applicable to any form of cardiac disorder should be considered in detail.

Apart from these, treatment of persistent auricular fibrillation resolves itself into the consideration of the employment of the digitalis group of

drugs, or of quinidine. The ultimate object of the employment of either is the same, namely, to regain the degree of cardiac efficiency which existed prior to the onset of the abnormal rhythm. This in the main depends upon the restoration of the pre-existing ventricular rate. The functions of digitalis and of quinidine differ. The primary object of administering digitalis in auricular fibrillation accompanied by a rapid ventricular rate is to reduce and, later, control the ventricular rate within normal limits; the drug has no effect upon the auricular fibrillation itself. The primary object of administering quinidine, on the other hand, is to arrest the auricular fibrillation; in other words, to restore the normal rhythm, and any beneficial effect of the drug is due to this.

In considering which drug should be employed, as well as the methods of their administration, the reader is referred to pages 865–868 and 870–872. With regard to the former, the following may be added: The degree of response to digitalis is an important consideration, a manifestation on the part of the patient of a particular intolerance to this drug being a point in favour of quinidine. The absence of indications of cardiac failure does not necessarily mean that this drug should not be tried, as cardiac failure may supervene later on. Other considerations are the risk—amounting to a possible fatal issue—attending the administration of the drug, the degree of probability of restoration of the normal rhythm, the probable degree of success resulting from this, and the degree of probability of relapse. In a small proportion of cases after the restoration of the normal rhythm, the general health of the patient is even worse. Cases for the administration of the drug should be selected with great care. We are justified in taking a comparatively small risk, while in doubtful cases we should clearly put the pros and cons of this method of treatment to the patient or his friends. Lastly, it should be remembered that if quinidine fails, digitalis medication is still open to us. In conclusion, the digitalis group of drugs is indicated in the great majority of cases of auricular fibrillation, quinidine being reserved for special cases.

The treatment of paroxysmal auricular fibrillation is that of paroxysmal tachycardia.

The treatment of auricular fibrillation associated with thyrotoxicosis is discussed on p. 998.

AURICULAR FLUTTER

Auricular flutter is a specific clinical condition, comparatively rare, in which a marked acceleration of the rhythmic co-ordinate contraction of the auricles occurs. It was first demonstrated clinically by Ritchie in 1905.

The rate of the contractions of the auricle may vary from 180 to 360, the usual rate being about 300, per minute. The ventricular rate varies considerably in different cases, this depending upon the auricular rate and the ability of the auriculo-ventricular junctional tissues to receive and transmit the impulse from the auricle. Very rarely the ventricle responds to each auricular contraction, resulting in 1 : 1 rhythm. In the vast majority of cases, however, there is partial heart-block or, very rarely, complete heart-block. In the former case there is usually a constant and uniform ratio between the auricular and ventricular rates, this varying from 2 : 1 to 5 : 1, the former being the

most frequent. In some cases, on the other hand, the response of the ventricle to auricular contraction is at irregular intervals, giving rise to irregularity of the pulse rhythm, which may be very irregular.

The commencement of auricular flutter is sudden. The condition may be paroxysmal or permanent. In the case of the former the paroxysm may last only for a few beats, or up to a few days, a few weeks, or, rarely, even months. The termination of a paroxysm is sudden. The patient may never have another attack; or attacks may recur at varying intervals, frequent or long. When once a patient has suffered from an attack of auricular flutter, there is a tendency to its recurrence from time to time. Paroxysmal auricular flutter may be succeeded by the normal rhythm, or sometimes by auricular fibrillation, the latter occurring during the administration of digitalis or apart from the use of the drug. There may be alternation of auricular flutter, the normal rhythm and auricular fibrillation, the changes taking place suddenly, and occurring from day to day or even for a few moments. Either auricular flutter or auricular fibrillation may ultimately become permanently established.

In persistent auricular flutter, the ventricular rate may diminish as the result of the occurrence of partial heart-block, and this may take place during the administration of digitalis or apart from the use of this drug.

Ætiology.—The ætiology of auricular flutter is similar to that of auricular fibrillation (see p. 896). It would appear however that, taking cases as a whole, it occurs at a somewhat later age; males are more often affected; rheumatic heart disease is less frequent and chronic myocardial disease more common; and thyrotoxicosis is a somewhat less common cause.

Pathology.—See pp. 896, 897.

Symptoms.—The symptoms of auricular flutter depend upon the ventricular rate, the duration of the condition, and the degree of integrity of the myocardium.

When there is marked tachycardia, the symptoms are similar to those of paroxysmal tachycardia (see pp. 892, 893). In the rare cases of 1 : 1 rhythm, the onset may be ushered in by giddiness, faintness, or even loss of consciousness. In those in which there is a material degree of, but not marked, tachycardia, usually the patient is conscious of the action of the heart; and after some time, in the great majority of cases, indications of cardiac failure supervene, or, if these were present before the onset, they increase in severity. In those in which there is an absence of a material degree of tachycardia, very frequently the patient is unconscious of the action of the heart; and there may be only slight, if any limitation of the field of cardiac response.

The rate and rhythm of the arterial pulse vary in different cases and, it may be, at different times in the same case. If the ventricle responds to each auricular contraction, the ventricular rate is exceedingly rapid, and graphic methods are usually necessary to determine it. In the vast majority of cases, however, partial heart-block is present, and as 2 : 1 rhythm is the most usual, a ventricular rate of 120 to 150 is frequently found. In other cases of partial heart-block, the ventricular rate may not be much increased, and, indeed, there may be even bradycardia, as in 4 : 1, or more partial heart-block, as well as in complete heart-block. When there is a constant and uniform ratio between the auricular and ventricular rates, the rhythm of the arterial pulse

is regular; in these cases, however, if the ventricular rate be above 150, pulsus alternans may be present. When, as is not infrequently the case, the response of the ventricle to auricular contraction is at irregular intervals, there is irregularity of the pulse rhythm; indeed, in some of these cases the sphygmogram may somewhat resemble that from a case of auricular fibrillation, detailed measurements being necessary for the purpose of differential diagnosis. An irregular pulse often becomes regular and more rapid as the result of exertion, due to the occurrence of 2 : 1 rhythm. On inspection of the neck, the jugular veins may be distended, and no pulsation visible; or very rapid movements may be evident.

A tracing of the jugular pulse differs in outline according to whether the ventricle responds to each auricular contraction, or to the degree of heart-block which may be present. In the former case there is usually a single wave. When the ventricle responds alternately to the auricle, there are two *a* waves to each ventricular beat, and these usually fall within the limits of ventricular systole. In 3 : 1 rhythm the character of the jugular pulse may be seemingly that of normal cardiac action, and it is particularly in these cases that an electro-cardiographic examination is required to establish the diagnosis. As has been already noted, complete heart-block is rarely found.

Diagnosis.—The diagnosis of the condition rests on the detection of the extremely rapid contractions of the auricle, and not infrequently this is impossible without the employment of the electro-cardiograph.

We should consider the possibility of auricular flutter (or of paroxysmal tachycardia) whenever an individual complains of attacks of palpitation, or is conscious of a marked increase in the cardiac rate, in either case occurring suddenly and without apparent cause, or suffers from indications of cardiac failure coming on rapidly, if the rhythm of the pulse be regular.

Auricular flutter with continuous 2 : 1 auriculo-ventricular block should be distinguished from sinus tachycardia and paroxysmal tachycardia. In the case of the first, the same considerations apply as in paroxysmal tachycardia (see p. 893). In the differential diagnosis between flutter and paroxysmal tachycardia, the following should be noted: If the cardiac rate is above 160, the condition is more likely to be paroxysmal tachycardia. In flutter, pressure on the carotid sinus often causes transient slowing of the cardiac rate, or even long pauses, especially if digitalis is being administered; strenuous physical exertion may convert the 2 : 1 into 1 : 1 rhythm, with resultant precise doubling of the rate; the condition is usually of longer duration; and the response to the digitalis group of drugs is notable.

If the rhythm be irregular, it is necessary to consider whether the case may not be one of auricular fibrillation. In this connection, *if a sphygmogram from a case of auricular flutter be carefully studied, it will be found that even though the ventricular rhythm is very irregular the pulse-beats measure out into groups of equal length, whereas this is never the case in auricular fibrillation.* The polygraph and electro-cardiograph are of notable assistance in the differential diagnosis. The diagnosis of auricular fibrillation with a markedly exaggerated ventricular rate in which the irregularity is only slight from auricular flutter should also be considered. Irregularity due to the presence of extra-systoles should also be excluded. Cases of auricular flutter in which the auriculo-ventricular ratio is constantly 3 : 1 to 4 : 1, so that the ventricular rate is not much, if any, increased, and in which the ventricular rhythm is

regular, are easily missed. The use of the electro-cardiograph is necessary in such cases.

Prognosis. — **The prognosis of auricular flutter resembles that of paroxysmal tachycardia. It is, however, more responsive to treatment.**

Treatment.—The ætiology should be reviewed, with the object of treating any associated condition, and the various therapeutic measures applicable for any form of cardiac disorder should be considered.

Apart from this, the treatment of persistent auricular flutter consists of the administration of digitalis, or of quinidine. The former should be tried first (see pp. 865, 868). I generally advise digitalis medication until almost full digitalization has been obtained. If the disorder persists, the dosage should be gradually diminished to a moderate or even small one, and this continued for a time, in the hope that the flutter may cease. If unsuccessful, this method may be repeated after a short interval. If the flutter still continues, the question of quinidine, with the object of terminating the condition, should be considered. This subject is dealt with on pp. 870–872. If,

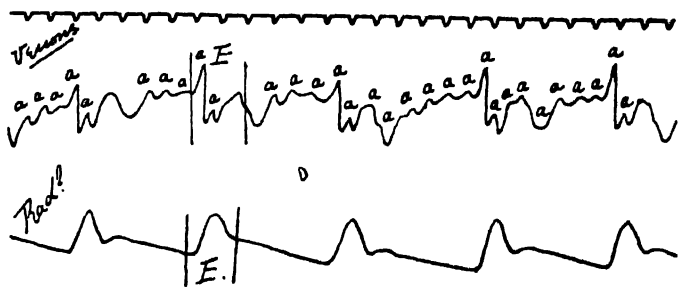

Fig. 33.—Simultaneous tracings of the jugular and radial pulses from a patient with auricular flutter fully under the influence of digitalis. The auricular rate is 382, and the ventricular rate is 50, per minute.

on the other hand, almost full digitalization induces auricular fibrillation, digitalis may be discontinued for some days, in the hope of a return to the normal rhythm. If this does not occur, treatment resolves itself into the consideration of the employment of digitalis, or of quinidine.

The treatment for the prevention of the recurrence of the attacks is the same as in the case of paroxysmal tachycardia.

The treatment of auricular flutter associated with thyrotoxicosis is discussed on p. 998.

VENTRICULAR FIBRILLATION

In ventricular fibrillation co-ordinate contraction of the ventricles is replaced by inco-ordinate contraction. It is a frequent cause of sudden death.

The condition may be induced experimentally by electric and other kinds of stimuli, by ligature of a coronary artery or one of its main branches, and by massive doses of digitalis, strophanthus, quinidine, or of adrenaline.

It is very rarely met with clinically, but may occur in coronary occlusion and angina pectoris; as the result of poisonous doses of the drugs mentioned; following auricular fibrillation, multiple extra-systoles, or ventricular paroxysmal tachycardia, and in complete auriculo-ventricular block; in certain acute infective diseases, particularly diphtheria; and in chloroform anæsthesia.

In ventricular fibrillation there is sudden loss of consciousness, and death almost invariably takes place.

It is believed that the tendency to the condition is lessened by the administration of quinidine, in moderate dosage; and that if the condition does occur, massage of the heart, if practicable, is sometimes effective.

HEART-BLOCK

By heart-block is meant defective conductivity or conduction of the heart. It may be divided into: (1) Sino-auricular block; (2) auriculo-ventricular block; (3) bundle-branch block; and (4) arborization or intra-ventricular block.

It should be pointed out that some writers use the term intraventricular block to include bundle-branch block and arborization block.

Sino-auricular Block

Sino-auricular block is a rare condition, in which the whole heart, *i.e.* both the auricle and the ventricle, fails to beat, due to an impulse in the sino-auricular node not being generated, or possibly the auricle failing to respond to such.

The condition may be met with in digitalis poisoning, and during the administration of quinidine. It is chiefly of vagal origin, and is abolished by atropine and exercise. It is occasionally associated with auriculo-ventricular block.

The interruption may occur occasionally or more frequently; or regularly after each normal beat; or, rarely, involving a succession of two, three, or more cycles. The first gives rise to an intermission of the pulse or a 'dropped' beat. The length of the long pause is usually rather less than the duration of two normal cardiac cycles, because a few cycles preceding it are rather quicker and a few after it are rather slower, resembling 'dropped beats' in the second degree of auriculo-ventricular block (see p. 903). The second results in halving of the cardiac rate. The third gives rise to a very long pause.

Rarely the condition gives rise to symptoms of cerebral anæmia, such as giddiness, faintness, or even actual syncope. When two, three, or more cycles are implicated, Adams-Stokes syndrome may occur.

In a polygram and an electro-cardiogram there is an absence of evidence of auricular and ventricular contraction during the long pause.

Sino-auricular block should be distinguished from sinus arrhythmia, extra-systoles, and partial auriculo-ventricular block.

Auriculo-ventricular Block

In auriculo-ventricular block, there is defective conductivity or conduction of the auriculo-ventricular node, or bundle above its division, or both.

There are three grades of auriculo-ventricular block: (1) In the first, the transmission of the wave of excitation from the auricle to the ventricle is merely delayed, resulting in a prolongation of the interval which separates the commencement of the contraction of the auricle and that of the ventricle, each impulse from the auricle reaching the ventricle, which duly responds. (2) The excitation wave from the auricle does not always reach the ventricle. (3) No impulses reach the ventricle from the auricle, so that the auricles and ventricles beat independently of each other, the former in response to impulses arising in the sino-auricular node at an approximate rate of 72 per minute; and the latter as the result of impulses arising in the auriculo-ventricular junctional tissues, generally in the auriculo-ventricular bundle between the site of the lesion and the division of the bundle into two branches, at a rate of about 30 per minute, which is the normal ventricular rate.

According to some writers, the first and second grades together constitute partial or incomplete heart-block, the first being called depressed conductivity; while other writers limit the former term to the second grade. The third grade is called complete auriculo-ventricular block.

First Degree of Heart-Block.—This grade of heart-block may give rise to irregularity of the pulse on account of variations in the length of the *As–Vs* interval. Some writers believe that contraction of the auricle produces a faint muffled sound, and that consequently when there is a slight delay between the auricular and ventricular contractions there may be a reduplication of the first sound, while if the delay be considerable, so that the contraction of the auricles falls in early diastole, there may be a reduplication of the second sound. In cases of mitral stenosis unaccompanied by auricular fibrillation a slight interval between the systolic murmur and the next first sound, is sometimes to be noted. In a polygram and an electro-cardiogram (leads I and III of Fig. 78) there is merely an increase in the *As–Vs* interval, this exceeding $\frac{1}{5}$th of a second.

Second Degree of Heart-Block.—In this condition what are called 'dropped beats' occur. These may be only occasional, or they may be more frequent. Or each third or fourth impulse may fail to reach the ventricle; in the former case the ventricular beats are grouped in twos, and in the latter they are grouped in threes, and in this way a bigeminal or trigeminal pulse results. Or every other impulse may fail to reach the ventricle, giving rise to halving of the ventricular rate, the condition being spoken of as 2 : 1 rhythm (lead II of Fig. 78); or only each third or fourth auricular impulse may be transmitted to the ventricle, resulting in 3 : 1 or 4 : 1 heart-block. In some cases certain ratios alternate.

It might naturally be supposed that the length of the prolonged pause during a dropped beat would be equal to two regular pulse-beats; such, however, is usually not the case for the following reason. There are variations in the *As–Vs* interval in association with dropped beats, there being a progressive increase of the *As–Vs* interval preceding and a progressive shortening of the interval following each dropped beat; the former is due to the increasing difficulty the impulses from the auricle have in reaching

the ventricle, and the latter to the rest which the ventricle has experienced during the pause. The result of the progressive increase of the *As–Vs* interval prior to, and of the progressive shortening of the *As* to *Vs* interval after, the dropped beat is that the long pause becomes shortened. When, however, there are no variations in the *As–Vs* interval in association with a dropped beat, the length of the prolonged pause is equal to two regular pulse-beats.

2 : 1 heart-block gives rise to infrequency of the pulse-rate, the rhythm being regular. This grade of heart-block is sometimes continuous, but usually the ventricle responds from time to time to successive stimuli received from the auricle, the pulse-rate, therefore, being usually above 36 per minute.

On analysis of a polygraphic tracing it will be found that the *a* wave is present at uniform intervals, and is of more frequent occurrence than the *c* or *v* waves—it may be even twice, three, or more times as frequent, according to the degree of block; but, unlike complete heart-block, each *c* wave is preceded by an *a* wave.

Complete Heart-Block.—Here the pulse-rate is slow, usually not more than 36, and not infrequently between 20 and 30 per minute, though some cases have been recorded in which the rate has been up to 60 or more beats per minute; it is little influenced by physical exertion, emotion, pyrexia, or

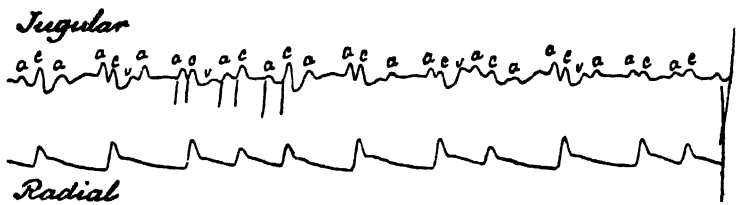

Fig. 34.—Simultaneous tracings of the jugular and radial pulses, showing partial heart-block. Note the progressive increase in the *a–c* interval of three successive rhythmic beats.

amyl nitrite, or, as a rule, by atropine. The beats are usually full and strong, and, as a rule, the rhythm is regular, the pulse being irregular, however, when extra-systoles are present. In a tracing of the radial artery, small waves occurring at regular intervals on the descending limb of the pulse-beat, probably due to auricular systole, may sometimes be noted. The systolic blood pressure is generally high, and the diastolic may be considerably diminished. There is usually evidence of hypertrophy of the left ventricle. On inspection of the neck, regular pulsations in the jugular veins, at considerably more frequent intervals than, and having a constantly varying time-relation to, those of the radial and carotid arteries and the apex-beat, due to auricular systole, may sometimes be noted; and in some instances a large pulsation in the jugular vein is seen from time to time when the auricular and ventricular contractions happen to coincide. On auscultation a first and second sound are found accompanying each contraction of the ventricle, and, in the opinion of most, faint muffled sounds may occasionally be heard over the præcordium during the long pauses, due to the contractions of the auricle. Some writers, too, have noted an accentuation of the first sound, synchronous with the

large pulsation in the jugular vein, when the auricular and ventricular contractions coincide.

If a polygraphic tracing be analysed, the disassociation of the auricular and ventricular rhythms is manifest. The *a* waves occur at regular intervals, and are more numerous than the *c* or *v* waves, and the time-relation of the *a* and *c* waves is a constantly varying one—the *a* waves at one time preceding, at another following, and at other times again coinciding with the *c* waves. When an *a* wave falls during the limits of ventricular systole its amplitude is increased. Extra-systoles may be present.

Ætiology and Pathology.—Auriculo-ventricular block is more frequent in males than in females. Taking cases as a whole, the most common causes are: (1) During the administration of full doses of digitalis; (2) fibrosis of the myocardium (see p. 949), more frequent in late middle and elderly life, and in males; and (3) in acute infective diseases, such as acute rheumatism, diphtheria, influenza, and pneumonia. In the case of the first and third, the lesser grades are more frequent; while in the second, the more severe degrees. In the first, the condition is temporary; in the third, usually so; and in the

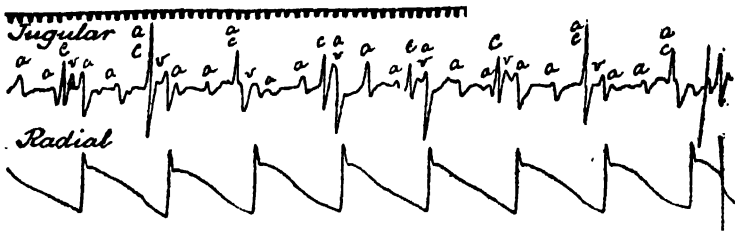

FIG. 35.—Simultaneous tracings of the jugular and radial pulses, from a woman aged 25, with severe heart failure, showing complete auriculo-ventricular block. The auricular rate is 88, and the ventricular rate 30, per minute.

second, it is generally persistent. Rarely complete heart-block is congenital, being associated with a defect in the auriculo-ventricular septum.

The most common pathological findings in heart-block are fibrosis of the myocardium and atheroma of the coronary arteries. Usually involvement of the auriculo-ventricular node or bundle is part of a widespread myocardial fibrosis, but occasionally the special artery to the bundle, a branch of the right coronary artery, is narrowed or occluded and the lesion is more limited. Syphilitic lesions are not common, and even in syphilitic patients atheroma of the coronary arteries may be the cause of heart-block. Acute inflammatory or degenerative changes are found when heart-block occurs during an acute infective disease.

Cases have been recorded in which no lesion could be demonstrated in the auriculo-ventricular node or bundle, and excessive vagal stimulation has been held responsible.

Symptoms.—There may be symptoms due to the associated cardiac lesion, whether myocardial or valvular, which are almost invariably present.

With regard to the block itself, in the case of 'dropped beats' the patient may be conscious of the long pause and of a thud following it, as in the case of extra-systoles. In the severe grades of partial and in complete block, he may complain of the forcible action of the heart. There may be

some degree, usually mild, of cardiac insufficiency, such as a sense of weakness, and early fatigue and shortness of breath on exertion, but the question arises whether this is due partly, or even wholly, to the associated morbid affection. Not infrequently Adams-Stokes syndrome occurs.

ADAMS-STOKES SYNDROME.—This, as originally described, is characterized by attacks of loss of consciousness and convulsions, both tonic and clonic, associated with marked infrequency of the ventricular rate. But the term may now be applied to various grades—from merely transient giddiness and faintness to the most grave condition of loss of consciousness due to cerebral anæmia the result of ventricular failure, which is not necessarily associated with marked infrequency of the ventricular rate, for very rarely it is due to sino-auricular block, ventricular fibrillation, or paroxysmal tachycardia.

The syndrome may be met with in one of the following conditions: (1) Partial heart-block, in which there occurs either an intermittent period of complete heart-block, resulting in a temporary standstill of the ventricles; or, rarely, merely a temporary increase in the grade of the partial heart-block, resulting in a temporary increase in the degree of the bradycardia. (2) Complete heart-block, in which the condition has become permanently established, especially if the ventricular rate is below 30 per minute. In these cases pauses of unusual length, due to temporary standstill of the ventricles, the result of diminished irritability of the ventricles, may occur. (3) Suddenly developed transient complete auriculo-ventricular block. Several cases of this kind have been reported. The conduction of the stimulus for contraction along the auriculo-ventricular junctional tissues is normal except that there is a liability to transient interruptions. (4) Very rarely in sino-auricular block, ventricular fibrillation, and paroxysmal tachycardia, especially the ventricular variety. Taking cases as a whole, Adams-Stokes syndrome is most commonly met with in patients with a severe grade of partial heart-block in whom complete block is developing. When complete heart-block has become permanently established, the ventricles apparently tend to become accustomed to the condition, and the pauses of unusual length referred to are not so likely to take place.

The severity of the symptoms depends principally upon the duration of the cerebral anæmia. It is generally believed that if this lasts two or three seconds, there is merely giddiness and faintness; if double that time, there is likely to be loss of consciousness; and if over about twelve seconds, there will probably be convulsions. There may be repeated seizures. There may or may not be a warning. In grave cases there is marked pallor or cyanosis, widely dilated pupils, and deep or even sterterous breathing. Usually the convulsions are confined to the face and upper limbs, the tongue is not bitten, and urine and fæces are not passed involuntarily. Within a few seconds of the cessation of the cerebral anæmia the colour and consciousness return.

Diagnosis.—The various grades of auriculo-ventricular heart-block are readily determined by means of the polygraph or electro-cardiograph, since these instruments afford separate records of the movements of both the upper and lower chambers of the heart. The first grade can only be recognised by means of either of these instruments, excepting that in cases of mitral stenosis unaccompanied by auricular fibrillation a slight interval between the auriculo-systolic murmur and the next first sound is sometimes to be noted. Fortunately they are not necessary in a considerable proportion of the other

cases. Thus, a diagnosis between occasional dropped beats, pulsus bigeminus, pulsus trigeminus, and infrequency, including halving, of the pulse rate—due on the one hand to extra-systoles and on the other to heart-block can almost invariably be made apart from them (see p. 890). It should be borne in mind that sinus irregularity and sino-auricular block may closely simulate occasional dropped beats due to partial heart-block. Lastly, auriculo-ventricular block should be distinguished from sinus bradycardia and auriculo-ventricular rhythm.

It is sometimes difficult to distinguish between partial and complete heart-block without the aid of the polygraph or electro-cardiograph. Most cases with a ventricular rate of 36 or under, however, are cases of complete heart-block. Moreover, the presence of more rapid pulsations in the jugular veins and of small waves occurring at regular intervals on the descending limb of a sphygmogram, and auscultatory phenomena afford help in differential diagnosis.

Adams-Stokes syndrome is easily recognised from the features described. It should be distinguished from the other causes of loss of consciousness and convulsions.

Prognosis.—Much depends upon the cause and any associated morbid affection. The occurrence of partial heart-block during the course of an acute infective disease is a sign, and may be the only sign, of myocardial involvement. Persistent heart-block of mild degree also is indicative of myocardial damage. With regard to persistent heart-block of severe degree, there are two questions of importance in considering the prognosis, namely—(1) Whether there is involvement of the heart muscle as a whole, and if so it is progressive; and (2) is the patient subject to syncopal attacks, and, if so, what is their severity and frequency? In the absence of both, and when also the patient does not suffer from syncopal attacks, the span of life may be prolonged for many years, and he may be able to live a fairly active life without inconvenience. But when the opposite is the case, especially if the syncopal attacks are severe and frequent, life is always in danger; and, apart from the risk of a fatal termination during an attack, death may occur with the usual clinical picture of cardiac failure. A number of syphilitic cases have been recorded in which energetic anti-syphilitic treatment appears to have been rewarded with recovery.

Treatment.—The ætiology and any associated morbid condition should be thoroughly reviewed.

When heart-block occurs during the course of an acute infective disease, rest in bed is indicated. When there is reason to suspect that syphilis is the cause, appropriate and energetic treatment should be employed. Persistent heart-block of mild degree requires no treatment in itself. In persistent heart-block of severe grade it is of particular importance that the patient should live within the limits of his strength. Digitalis is contra-indicated in partial heart-block. It may be cautiously tried in complete block in which there is congestive failure.

Adams-Stokes Syndrome.—The patient should be warned to avoid anything known to predispose to the attacks, and, as far as possible, should be protected from the risks of falling.

For the prevention of the occurrence of the attacks, adrenaline and ephedrine are the most successful remedies. The first should be admin-

istered either subcutaneously or intramuscularly, from 5 to 10 minims of a 1 : 1000 solution thrice daily, failing which, every few hours. Ephedrine differs from adrenaline in that its effect persists for several hours, and, moreover, it has the advantage of being effective when administered orally. I have found barium chloride, administered by the mouth, apparently undoubtedly effective in three cases, one of which was extremely severe. The drug increases the irritability of the heart muscle. It may be given in pill form, at first in doses of $\frac{1}{2}$ gr. twice daily and, if necessary, cautiously increased to 1 gr. thrice daily but stopping short of toxic symptoms. If unsuccessful alone, it may be tried in combination with adrenaline. Thyroid appears to be sometimes of value and may even be completely successful. Potassium iodide, by its depressing effect on the ventricular muscle, may even aggravate the condition when the cause is other than syphilis. Atropine is indicated in cases of partial heart-block in which there is vagal over-activity.

If an attack occurs, adrenaline is the only potent therapeutic measure at our disposal, but is contra-indicated in the very rare cases of ventricular fibrillation. It is necessary to point out that when—as in the vast majority of cases—the attack is due to a temporary standstill of the ventricles, with consequent temporary cessation of the circulation, intracardiac injection is necessary, because the beneficial effect of the drug is due to its action in stimulating the sympathetic nerve endings in the heart muscle. The dose should be 0·5 to 1 c.c. of 1 : 1000 solution. In the rare cases in which the attacks are due to merely a temporary increase in the grade of an existing partial heart-block, the drug may be effective even if given subcutaneously or intramuscularly.

Bundle-Branch Block

Bundle-branch block is relatively uncommon. If complete, there is a complete interruption of the wave of excitation along either of the two main branches of the auriculo-ventricular bundle. The excitation wave is transmitted to the two ventricles along the branch which is unaffected. There is slight asynchronism of the contraction of the two chambers. The condition may be persistent or temporary. According to the new nomenclature, the left branch is much more frequently affected.

Auriculo-ventricular block, and less frequently auricular fibrillation (Fig. 81), may co-exist.

The ætiology and pathology of bundle-branch block are the same as those of complete auriculo-ventricular block, excepting that perhaps the former condition is more common in the elderly and in males; is more frequently associated with hypertension, chronic myocardial disease, and atheroma of the coronary arteries; occasionally is associated with coronary occlusion; and is also more often organic.

The subjective symptoms are not distinctive. There may be a visible and palpable bifid apex-beat, and reduplication of the first sound at the cardiac apex, or between this point and the left border of the sternum, so that three sounds are audible. In the opinion of most, the third sound is presystolic in time, but in that of some, it is systolic. Reduplication is still present when there is complete auriculo-ventricular block, or auricular fibrillation. There is sometimes pulsus alternans.

Bundle-branch block should be thought of whenever the foregoing physical signs are present. It is to be noted, however, that these may be met with in other conditions. A diagnosis may be made with certainty by means of the electro-cardiograph.

In persistent left bundle-branch block, apart from relatively few exceptions, the prognosis is very serious, a fatal termination occurring within at the most two years in the majority of cases. In right bundle-branch block, the outlook is very much less unfavourable. In the case of both, much depends upon the degree of cardiac failure.

With regard to incomplete or partial bundle-branch block, see p. 1021.

Functional Bundle-Branch Block

This is a rare condition in which there is increased duration of the Q. R, S group of deflections together with a diminished P–R interval. It is met with in young healthy individuals who tend to have paroxysmal tachycardia. It is considered highly probable that the abnormal electro-cardiogram is really not due to functional bundle-branch block, and it is thought that there is a special path of conduction from the sino-auricular node or its neighbourhood to either of the ventricles, and that in the same individual sometimes the wave of excitation travels along this channel and at other times along the normal one. So far, however, there is an absence of post-mortem findings. The electro-cardiographic features may sometimes suddenly cease, either spontaneously, or with physical exertion or the administration of atropine.

Arborization or Intraventricular Block

In this, there is diminished conductivity of the subendothelial arborizations of the Purkinje system. The ætiology and pathology are similar to those of bundle-branch block. In the vast majority of cases the condition is associated with widespread chronic myocardial disease. It is believed by some that the affection may be recognised by means of the electro-cardiograph (see p. 1021).

The prognosis is even more serious than that of bundle-branch block, being almost always grave.

PULSUS ALTERNANS

Definition.—By pulsus alternans is meant a condition of the pulse in which a larger beat and a smaller beat alternate. Sometimes the smaller beats are slightly delayed, but they are never premature.

Ætiology.—The condition is usually transient, but may persist for some minutes, hours, days, or weeks. The former generally occurs for a few cycles immediately following an extra-systole, but it may be with an increase in the cardiac rate brought on by physical exertion, in both instances being usually slight or moderate. Persistent pulsus alternans occurs in two sets of circumstances, namely: (1) a marked acceleration of the cardiac rate in auricular flutter or paroxysmal tachycardia; and (2) in failure of the left ventricle, in the great majority of cases in those over middle age and due to the causes mentioned on p. 853, but sometimes in younger people

with post-rheumatic valvular disease, and occasionally in pneumonia and other acute illnesses.

Pulsus alternans is increased or may be induced by an acceleration of the cardiac rate, and may be diminished or disappear with the decreased rate.

The condition is indicative of depressed contractility.

Symptoms.—The pulsus alternans in itself causes no subjective symptoms, but when associated with left ventricular failure manifestations of the latter are present (see p. 857). Sometimes the smaller beats are so feeble that no waves are transmitted to the wrist, resulting in infrequency of the pulse.

Diagnosis.—Gross alternation of the pulse can usually be recognised by the finger. Lesser grades can be readily detected by the sphygmomanometer, preferably by the auscultatory method. The pressure in the armlet is raised until the pulse below it disappears, and then lowered very gradually. The larger beats reappear at a higher pressure than the smaller beats, so that just below the systolic level the pulse-rate is halved. In extreme cases the difference in pressure between the larger and smaller beats may be 20 to 30 mm., but usually it is only 1 to 5 mm. A radial tracing is valuable in distinguishing

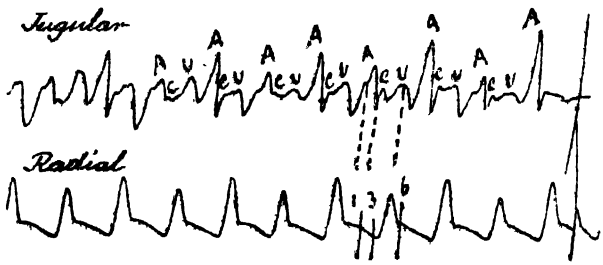

FIG. 36.—Simultaneous tracings of the jugular and radial pulses, showing continuous pulsus alternans.

pulsus alternans from extra-systoles. In the former the beats are evenly spaced, excepting that sometimes they are slightly delayed; whereas in the latter they are premature and the pause following the smaller beat is longer than that after the larger one.

The condition is sometimes but not usually evident in an electro-cardiogram.

Prognosis.—When the pulsus alternans occurs apart from a marked acceleration of the cardiac rate, it is an indication of severe or even extreme exhaustion of the heart muscle. When the condition is persistent, death may follow within a few months, or at most a few years. When transient, the exhaustion may be only temporary but even in these cases the prognosis should be guarded. When the condition is associated with marked tachycardia, it appears to be of relatively minor significance in itself.

Treatment.—When unassociated with marked tachycardia, complete rest, physical and mental, is urgently indicated, and if the condition is persistent this should be long-continued. The left ventricular failure should be treated on the lines discussed elsewhere. It is to be noted that digitalis is not contra-indicated.

FREDERICK W. PRICE.

CARDITIS: THE RHEUMATIC INFECTION OF THE HEART IN CHILDHOOD

Definition.—By carditis is meant inflammation involving the endocardium, the myocardium, or the pericardium, or the three simultaneously.

Before dealing with endocarditis, myocarditis and pericarditis individually, it may be advisable to discuss the rheumatic infection of the heart in childhood. This is a subject of great importance, for by far the larger proportion of cases of heart disease under 30 years of age, and a considerable proportion of those of later life, are the direct result of this infection.

It is necessary to point out that even yet rheumatic infection of the heart in childhood is very frequently overlooked. The two chief reasons are: (1) the clinical picture of acute and subacute rheumatism was originally drawn from the disease as it appears in adult life, whereas in childhood it presents many and important points of difference; and (2) even when a rheumatic infection has been diagnosed, it is sometimes exceedingly difficult to come to a definite decision as to whether the heart is involved or not.

It is important to bear in mind the following facts: In adult life arthritis is the chief manifestation of the rheumatic infection, and is looked upon as constituting a typical attack, while cardiac involvement is regarded as a complication. In children, on the other hand, arthritis is often vague in character, and may be entirely absent, while affections of other parts are more frequent, and constitute a more conspicuous feature in the disease. Thus, sometimes the affection is confined to the tendons or the fascia in the neighbourhood of the joints. What are called 'growing-pains' are frequently of rheumatic origin. Subcutaneous nodules, various erythemata and purpura rheumatica are more frequent manifestations of the rheumatic infection. Chorea is a common indication. Tonsillitis is perhaps more commonly rheumatic than in adult life. There may be unexplained pyrexia. Lastly, cardiac involvement is a much more frequent manifestation of the rheumatic infection in childhood than in adults; it is at least as frequent an indication as any other, and should not be regarded as a 'complication'; and it may occur in association with any of the foregoing, or with an indeterminate febrile attack, or alone—that is, it may be the only manifestation of rheumatism. Another point to bear in mind is that while rheumatic carditis may occur acutely in children, it often does so in a subacute and insidious form. Not rarely there is a total absence of subjective symptoms. Or, if such be present, they are often masked by other manifestations of the rheumatic infection. Pallor, fatigue, loss of appetite and wasting may be the first symptoms. Sometimes the onset is accompanied by a rise of temperature above that already existing, this increased pyrexia occurring without any increase in the arthritic symptoms. The usual cardiac symptoms may be present (see Endocarditis, Myocarditis and Pericarditis). The diagnosis rests mainly on physical signs, together with the results of electro-cardiographic examination, and the existence of the condition is frequently unsuspected until the heart is examined. The physical signs, however, are not infrequently slight and vague in character, and the diagnosis is consequently often attended with extreme difficulty.

In view of the foregoing, it is clear that when in a child there is even a suspicion of rheumatic infection, he should at once be put to bed, and a most careful clinical examination of the heart made daily and an electro-cardiogram be taken every few days, and if there be any doubt whether the organ is involved or not, he should be kept in bed until this has been set at rest.

In cases in which a definite diagnosis of carditis has been made, a most difficult question which may have to be decided later on is whether *active* carditis still persists or not. In this connection the sleeping pulse-rate is of value. If there is active carditis, the sleeping pulse-rate remains raised and may even equal the pulse-rate when the child is awake, while in the tachycardia of nervous origin, the sleeping pulse-rate is normal. The sedimentation rate of the red blood cells is also used for this purpose. It is increased in the active stages of the disease, and falls to normal when activity ceases.

ENDOCARDITIS

Definition.—By endocarditis is meant inflammation of the lining membrane of the heart. In the great majority of cases the inflammation involves chiefly the endocardium of the valves, and is not infrequently so limited. The term valvulitis is applied to endocarditis of the valves, while inflammation of the endocardium lining the cavities of the heart is referred to as mural endocarditis. The surface of the valves next the blood stream, namely, the ventricular surface of the semilunar valves and the auricular surface of the auriculo-ventricular valves, is affected. In adults the left side of the heart is far more commonly affected than the right, the mitral valve being more frequently attacked than the aortic; while, on the other hand, during fœtal life the opposite is the case. Some degree of myocarditis is probably always present with endocarditis.

A satisfactory classification of endocarditis is not easy, that most commonly adopted being as follows: (1) Acute, (*a*) simple, and (*b*) septic, infective, ulcerative or malignant; and (2) chronic or sclerotic. It should be noted that it is impossible to draw a sharp line of distinction between these varieties on grounds of ætiology, pathology, or morbid anatomy. Clinically, however, the distinctive features of each are fairly marked, although even in this case the distinction is not absolute. More recently a subacute variety, ulcerative in character, has been described (see Septic Endocarditis).

Acute Simple Endocarditis

Ætiology.—Acute simple endocarditis occurs most commonly in childhood and adolescence. It is rarely, if ever, a primary disease. Acute and subacute rheumatism, in one of its forms (see p. 913), account for the great majority of cases. Scarlet fever is occasionally the cause, while pneumonia, typhoid fever, small-pox, and wasting diseases are responsible for a certain number of cases.

Pathology.—The mitral valve is the most commonly affected, the next in frequency being the aortic, and the third both the aortic and mitral valves. In this form of endocarditis the parts affected become swollen, as the result of œdema and connective tissue proliferation, and cauliflower-like or warty

excrescences, varying in size from that of a pinhead to a bean, called vegetations, make their appearance on the segments of the valve or on the mural endocardium. The valvular vegetations are usually not situated at the extreme margins of the cusps, but at those parts which come into apposition during closure, namely, a short distance from their margins. The vegetations consist of blood platelets, leucocytes and fibrin. In rheumatic endocarditis *Aschoff's nodes* (see p. 289) are sometimes found in the inflamed valves. Various micro-organisms have been described in association with the vegetations, but they are not present in large numbers and may be absent, and even if present it is not certain that they are the cause in this form of endocarditis. Fragments may become detached from the affected valves, be carried by the blood to remote parts, and ultimately become impacted in a vessel; this process is known as embolism, and the impacted fragment as an embolus. This may result in obstruction of the circulation, and (1) necrosis, or hæmorrhage, or both, within the area of distribution of the occluded vessel, and the formation of infarcts; or (2) gangrene of the area supplied in the case of one of the larger arteries of the limbs. Infarction most generally occurs in the spleen or kidneys, although it is not infrequently found in the brain or its membranes, the retina, lungs (in right-sided endocarditis), intestines and skin.

The myocardium is involved, in varying degree, in at least most cases and perhaps in the great majority, but the involvement is permanent only in a certain proportion.

An attack of acute simple endocarditis is in the great majority of cases followed by the formation of fibrous tissue; in a certain proportion of cases by septic endocarditis; or possibly, in rare instances, by resolution. In the case of the first, the fibrous tissue tends to contract as time advances, giving rise to various deformities of the valves and ultimately to permanent stenosis, or incompetence, or both combined.

Symptoms.—In the first place, the reader is referred to the remarks on p. 913.

The patient may suffer from shortness of breath, palpitation, and discomfort or pain in the præcordium; and if there is involvement of the myocardium there may be manifestations of pronounced cardiac failure.

The onset is sometimes accompanied by a further rise of temperature without any increase in the symptoms of the causative disease. The degree of the pyrexia due to the cardiac affection is usually not marked, but occasionally there is a sharp rise of temperature. The cardiac rate is generally increased. There may be irregularity of rhythm (see p. 916), the result of implication of the myocardium.

In the early stages the apex-beat may be rather excited in character. Later, however, and in some cases even quite early, there may be physical signs of dilatation of the heart, generally both-sided (see p. 857). The first sound in the mitral area may become slightly prolonged, or roughened, or may exhibit a lack of clearness; and within 24 hours it may be accompanied by a distinct murmur, soft in character. Later, the second sound in the pulmonary area may become accentuated and even reduplicated. In the case of the aortic valve, the second sound may become altered; and—later, a soft-blowing murmur may accompany it, usually either along the left border of the sternum from the level of the second to the fourth intercostal spaces, or over the sternum between the level of the second rib to the fourth

space. A short and accentuated first sound at the apex, and an accentuation and it may be reduplication of the second sound in the pulmonary area are believed by some to be early signs of mitral stenosis, but excitation of the cardiac action should be excluded. A presystolic murmur at the apex usually does not make its appearance until some time after the onset of the rheumatic infection, the mitral orifice having become permanently stenosed. If there is considerable dilatation of the left ventricle due to myocarditis there may be a soft-blowing diastolic murmur in the mitral area—the so-called relative or functional mitral stenosis (see p. 938).

If there is severe carditis there may be even severe cardiac failure, usually both-sided, with considerable and rapid dilatation, even early in the disease.

There is usually a moderate leucocytosis and sometimes a slight secondary anæmia. Embolism may occur.

Diagnosis.—The diagnosis of acute simple endocarditis is often a matter of great difficulty. We should suspect its existence when there is an increase in the cardiac rate and in the degree of pyrexia without any aggravation of symptoms of the causative affection; or when tachycardia and pyrexia persist without an apparent cause; or when there are subjective symptoms together with acceleration of the cardiac rate and the existence of a murmur not previously present. The occurrence of auriculo-ventricular block during the course of an acute infective disease indicates involvement of the myocardium, and auricular fibrillation and extra-systoles are suggestive.

Evidence of dilatation of the heart and a recently developed apical systolic murmur do not necessarily signify acute endocarditis, for these may be found in any acute febrile disease, and in acute myocarditis. The character of a systolic murmur is of some diagnostic value, a soft-blowing one being in favour of endocarditis. Accentuation of the second sound in the pulmonary area later in the illness is also suggestive of mitral incompetence. An aortic systolic murmur is not so suggestive of acute endocarditis as is a mitral, while a pulmonary systolic may be almost disregarded. The reader is also referred to the other physical signs described above.

It is necessary to distinguish the murmur of acute endocarditis from that due to previously existing valvular disease. The existence of subcutaneous nodules or pericarditis, the sudden appearance of partial heart-block (indicative of coincident acute myocarditis), or the appearance of new murmurs or the disappearance of old ones, is in favour of a fresh attack of acute endocarditis, whether simple or infective. Embolism is not pathognomonic of acute endocarditis, as it may occur in chronic valvular disease, especially in mitral stenosis. In acute endocarditis, however, it is not infrequently multiple and recurrent, and is of more usual occurrence in the systemic than in the pulmonary circulation.

If acute endocarditis occur in an individual already the subject of valvular disease, the murmur is not of recent development, it is often loud or harsh, audible over a considerable area, and evidence of cardiac enlargement is usually present.

Prognosis.—The immediate prognosis of acute simple endocarditis is, as a rule, favourable, death being of rare occurrence; this may happen, however, if there be accompanying pericarditis or severe myocarditis. With regard to the ultimate prognosis, it has been pointed out that complete

resolution in all probability rarely occurs. Organisation is the usual sequel, ultimately giving rise to permanent stenosis, or incompetence, or both; in a certain percentage of these cases, the early murmur may disappear, and a permanent murmur may not become established until much later on, even several years. It should be noted that the future prognosis of a case of acute simple endocarditis largely depends upon whether convalescence is sufficiently prolonged. In a certain number of cases, ulceration of the valve results.

Treatment.—The treatment of a case of acute simple endocarditis is of great consequence, especially with regard to the future of the patient.

The indications are to endeavour to arrest the morbid process as early as possible, and to give the heart the best chance of the fullest possible repair.

The treatment of the causative disease should be adopted. For that of rheumatic fever, the reader is referred to pp. 293–296.

In all cases, after the manifestations of active disease have ceased, rest in bed is indicated for *at least* three months; this to be followed by an equal period of partial rest; and games should not be indulged in for another year.

During the first two months that he is confined to bed, the patient should keep as quiet as possible, physically and mentally, and should not be allowed to sit upright. Afterwards an extra pillow may be allowed, and a week or so later the back may be gradually more raised. After the period in bed, the patient should be moved to a couch, to which he should be confined for four weeks. During the latter half of this, passive movements, or gentle massage, or both, may be tried. Then slight walking exercises may gradually be attempted. If during any of these or later stages exertion be accompanied or followed by any abnormal subjective symptoms, or succeeded by maintained increased frequency of the pulse, the amount of exertion has been too much and should be proportionately reduced.

During the active stage of the disease small blisters applied frequently to the præcordium are advocated by some; and during the later stages the internal administration of sodium iodide is recommended. The results of the administration of digitalis are, as a rule, very disappointing, whether auricular fibrillation (or flutter) is present or not. If it is employed, caution should be exercised and large doses avoided.

Otherwise, the reader is referred to the various therapeutic measures described on pp. 861–873.

Convalescent Home Treatment.—Prolonged convalescence in special country homes devoted exclusively to children recovering from active rheumatic carditis is now advocated. The advantage of this form of treatment is that a return to normal life is made gradually, under skilled supervision, so that any indications of persistent activity of the disease or relapse may be quickly detected, and further complete rest promptly instituted. At some of these homes, facilities also for education are available, and this overcomes one of the greatest drawbacks of prolonged rest in children, namely, interference with education. Though this line of treatment is still on trial, considerable success has been reported in this country and America. A dry and elevated site is important. At some homes, treatment on the same lines as in the treatment of pulmonary tuberculosis is employed, the wards being so constructed that one side can be opened up.

It is well to examine a patient who has suffered from acute endocarditis

at regular intervals after the attack, and careful inquiry should be made as to his mode of life. In children, we should be especially on the look out for any rheumatic manifestation, and, as soon as detected, the condition should be immediately and adequately treated.

FREDERICK W. PRICE.

SEPTIC ENDOCARDITIS

Synonyms.—Infective Endocarditis; Ulcerative Endocarditis; Malignant Endocarditis.

Objections have been raised against each of these synonyms: that all endocarditis is infective, that ulceration is not invariable, and that some cases recover. But that some distinctive name is necessary to mark off a disease-process which is quite different from "simple" or "rheumatic" endocarditis is generally recognised. The assertion frequently made, that no sharp line of demarcation can be drawn between simple and ulcerative endocarditis, though true, does not dispose of the fact that in the great majority of cases the distinction is of fundamental importance and not very difficult of recognition.

The disease has an importance somewhat out of proportion to its frequency, partly on account of its great gravity and partly on account of the difficulties which often beset the diagnosis. The incidence of the disease in the wards of a large general hospital is about 1 in 170 cases.

Ætiology.—*Relation to rheumatism and other diseases.*—In more than half of all cases of the disease there is a clear history of acute or subacute rheumatism or of chorea. In the majority of these cases the patient has suffered from rheumatic endocarditis some time previous to his present illness, and has been left with definite and recognised valvular disease; in a few the condition of rheumatic endocarditis has passed directly, but often imperceptibly, into that of the septic condition. Usually the interval between the occurrence of the rheumatic fever and the onset of septic endocarditis is measured by several years, and these have been for the most part years of good general health. To those few cases in which the transition between the rheumatic endocarditis and septic endocarditis is a gradual one the term "malignant rheumatism" has been applied by some authorities. But the term introduced confusion in respect of the bacteriological questions involved, and is perhaps on this account to be avoided. Next in frequency to the rheumatic group of diseases in the patient's history, but insignificant in comparison, are scarlet fever, gonorrhœa, influenza, typhoid fever, malaria, syphilis, Graves's disease, dysentery and pneumonia.

Influence of congenital defects.—A congenital defect in the heart predisposes it to infection, apparently through the medium of that chronic thickening of the endocardium which is often found in connection with these defects. This factor has been definitely established in regard to the aortic valve.

Other ætiological factors.—Strain is present in some cases as a definite causative factor. This was seen in a series of cases which occurred in soldiers during the War of 1914–1918; these cases were aortic in the main, and in several of them there was no evidence of pre-existing valve lesions of an acquired nature.

Age.—The chief incidence is between the ages of 15 and 50. Out of 150 cases collected by the writer 122 occurred between these ages. One-half of all the cases occurred between 20 and 40, no doubt on account of the predisposition created by the presence of sclerosis of the heart valves after acute rheumatism, the chief age incidence of which is a decade earlier than this. The youngest case of the series was that of a child aged 2½ years, the subject of congenital heart defects. The oldest cases were those of a woman aged 64, and of a man aged 63, both of whom developed pneumococcus endocarditis with lobar pneumonia.

Sex.—This does not appear to be a determining factor.

Pathology.—The essential pathology in septic endocarditis is a progressive microbic infection of one or more of the heart valves, or of the mural endocardium. *The infecting micro-organisms*, as judged by positive blood cultures during life rather than by post-mortem investigations, are very variable. An analysis of 40 cases of the disease in which positive blood cultures were made during life showed streptococci in 26, pneumococci and Pfeiffer's bacillus in 5 each, gonococcus in 2, *Staphylococcus albus* in 1, and an unclassified micro-organism of bacillary form in 1. The *gonococcus* accounts for the infection in a few cases. If post-mortem results are taken, *Staphylococcus aureus* bulks largely in the analysis and the pneumococcus is represented more frequently. A few other organisms, relatively unimportant, also appear—*B. typhosus*, *B. coli* and *C. diphtheriæ*. Streptococci are certainly the most common organisms concerned, and the characters of those members of the group found in this disease deserve special attention. If we except acute cases due to *S. pyogenes* (*S. hæmolyticus*), the types of streptococcus most often found are not highly pathogenic, but of low virulence, such as are found in normal fæces and in normal saliva (*S. viridans*). They are for the most part short-chained cocci, not lethal for mice, and they yield a set of biochemical reactions that mark them off quite sharply from *S. pyogenes*. These facts harmonise with certain broad clinical and pathological observations and serve to explain them: the chronicity of many of the cases, and the latency of others; the scanty leucocytosis often seen; the apyrexial periods not infrequently present; the absence of suppuration in the embolic infarcts which is such a feature of the disease; the absence of any visible focus of infection in the great majority of the cases; the enormous number of living micro organisms that may be present in the blood stream at a time, it may be, when the patient is not acutely ill. The writer has shown that it is not difficult to set up a condition of septic endocarditis in the rabbit by the intravenous injection of "saprophytic" streptococci from healthy human saliva and fæces.

The condition of infection once established in the endocardium, a state of "arterial pyæmia" results, the circulation being fed by micro-organisms from the infected area. Minute vessels become plugged by masses of these microbes. Larger emboli, formed of pieces of the fungating vegetations, and of various sizes, add to the pyæmic process. Destructive and vegetative processes proceed together at the site of infection, which spreads to adjacent structures in the heart, both by contact and by direct extension. It has been shown that the micro-organisms in the blood stream are destroyed *in vitro* in 24 hours when citrated blood is incubated without culture media. This fact suggests that they are paid out into the blood stream from the

heart lesion, but that their duration of life in the former is short. It also explains the fact that blood cultures are not infrequently sterile.

Symptoms and Course.—The disease may be *latent*, and only discovered post mortem. It may be *fulminating*, in which case it may be suspected, but rarely diagnosed. In the fulminating cases the infection is usually by *S. aureus*, and the ulcerating endocarditis is only one part of the *S. aureus* pyæmia. Such is the endocarditis complicating acute osteomyelitis, and that seen in very acute pyæmia resulting from *S. aureus* infections of the skin. The more important types are the *acute* and *subacute*.

The acute form.—The onset is usually abrupt, often with a rigor, and the symptoms are those of an acute specific fever. Pain in, and swelling of, joints is common, with acid sweats, often leading to a disgnosis of rheumatic fever and calling for the use of salicylates. Not infrequently the failure of response to full doses of salicylates is the first observation to throw doubt upon the diagnosis. The pneumococcus cases are generally of this type, pneumonia or pleurisy with effusion being usually present; the patient remains very ill after the eighth day of his disease, infection of the endocardium being perhaps the most serious cause of absence of crisis. Gonococcus infection is also usually of this form; the temperature chart may show two "spikes" in the 24 hours. The duration of the acute cases is from 7 to 30 days. A very few cases undoubtedly recover.

The subacute type ("Subacute bacterial endocarditis").—This is probably the most common type of the disease. Attention has been drawn to it by Osler, Horder, Libman and others. The onset is gradual, often insidious, so that it may not be possible to determine with accuracy when the disease began; it seems certain that in many of the cases the process of endocardial infection has existed much longer than is suspected. The initial symptoms are general weakness with sweats and anæmia, or a condition somewhat resembling subacute rheumatism, or fever which is unexplained by the physical signs. The duration of these cases is very variable; from 2 to 6 months includes the majority of them; but a few may last for 12 months or even longer. The infecting micro-organisms are streptococci of the fæcal and salivary type (*Streptococcus viridans*, *Streptococcus endocarditidis*), Pfeiffer's bacillus and occasionally the pneumococcus. In some of these cases the pre-existing valve lesion is very slight, although its presence is generally known if the patient is of the private class.

The heart.—In the great majority of cases signs of valvular disease or congenital defect are present at the outset. In a few cases, signs of valvular defect appear during the course of the disease. Rarely, there may be no evidence of valvular disease at any time: this experience is almost confined to cases in which the infection is of a terminal kind, occurring in patients who are too ill to admit of thorough examination, or in whom there is early and considerable dilatation of the heart. As the disease progresses it is common to get evidence of the involvement of other valves than the one originally infected, such as the appearance of signs of aortic regurgitation in a case originally one of mitral disease. Undue importance is perhaps attached to changes heard in the character of the murmurs from day to day. When the heart symptoms are prominent, the case is said to be of the "cardiac type," and such a clinical picture does quite commonly present itself: in which event the patient has in most instances been a heart invalid for some time previ-

ously. But in a considerable proportion of the subacute cases it is a striking thing that the heart shows little recognisable defect, at least for a considerable time. For the greater part of its course it may be said that subacute septic endocarditis is very largely destitute of cardiac symptoms. Arrhythmia, signs of restriction of the field of cardiac response to effort, and the results of so-called congestive failure—not only may all of these be conspicuous by their absence; it is unusual to see them.

When the infection (often pneumococcal) involves the right side of the heart only, evidence of valvular disease is generally lacking, the symptoms and signs being mainly those of recurrent pleurisy, consequent upon pulmonary infarction, with or without liquid effusion.

Arterial embolism.—This event is extremely common and constitutes one of the cardinal signs of the disease. *The importance of the search for emboli and their effects in a suspected case cannot be overestimated.* But to obtain an adequate conception of the disease-process here considered it is necessary to enlarge considerably the earlier notions of the embolic process in two directions: the diffuseness of the embolic site and the minuteness of the embolic fragment. The skin shows two distinct lesions, both highly characteristic of the disease—(*a*) Petechiæ, varying greatly as to their number in different cases—there may be no more than two or three, and only discovered after careful search at the root of the neck, in the nail bed or beneath the conjunctiva, or there may be a great number, presenting an appearance as though the patient has been flea-bitten. (*b*) Discoloured areas, usually tender, and most often affecting the pads of the fingers or toes, coming and going in the course of a few hours or days. The appearance of one of these red areas is often accompanied by sudden pain or acute tenderness on pressure. These lesions are of considerable diagnostic importance. They do not occur in rheumatism.

In the kidney there may be gross embolic events leading to infarction and hæmaturia. Of equal if not of greater importance is the occurrence of very minute microbic embolisms in the glomeruli, leading to the appearance of red blood cells and traces of albumin in the urine, and ultimately to a state of embolic focal nephritis, demonstrable under the microscope post mortem (Bæhr; Gaskell). The earliest symptoms of the disease may be those of renal failure. The retina may be affected, exploration of the fundus revealing hæmorrhages. One of the most common seats of emboli of the massive kind is the spleen, leading to enlargement and usually a palpable organ. Acute and severe pain may occur with the event, and friction, due to perisplenitis, may be heard. Apart from embolus the spleen may be enlarged; a palpable spleen is of considerable diagnostic importance. The brain may suffer, the most common result being hemiplegia. The embolus may lead to infective arteritis, with subsequent aneurysm formation and hæmorrhage which may be abruptly fatal. The mesenteric vessels and those of the limbs are frequently involved, either the main artery, or, more often, its branches, and especially the radial and posterior tibial. Here, again, aneurysms may develop, and gangrene occasionally.

Pyrexia.—Fever is present in nearly all the cases, perhaps in all at some time or other in the course of the disease; but occasional afebrile periods may occur, lasting from 2 or 3 days up to a fortnight, in the subacute cases. In the acute cases a high continued fever is not uncommon, and when this

is so the patient is highly toxic and asthenic and the heart symptoms are apt to be in abeyance ('typhoid type'). Irregular remittent fever is the most common form, both in the acute and in the subacute types. A high and regular quotidian intermittent fever is not uncommon—the gonococcus cases are particularly prone to this variety of fever. Rigors are common in the fulminating and acute cases; they also occur in subacute cases when embolism is rife. Whatever the form of the fever the temperature is apt to take a lower range shortly before death. *A fall in the temperature, the patient remaining very ill, is of no service and must not be taken for a good prognostic.* Such a fall of temperature may occur when signs of renal inadequacy supervene.

The blood shows a progressive and ultimately severe anæmia. The degree of leucocytosis varies with the type of the disease. In acute cases it is generally high (20,000 to 40,000), though this, again, varies with the degree of the patient's response to the infection. In the subacute cases the leucocytosis is rather remarkably constant about the figures 9000 to 12,000. In a few cases there is leucopenia. Blood cultures are extremely important in the matter of diagnosis. And yet it not uncommonly happens in the subacute cases that the diagnosis is certain and no growth of micro-organisms is obtained. In the great majority of cases, however, positive blood cultures are obtained, given proper technique.

General state.—Loss of flesh is invariable, but rarely a marked feature. Pains are common, and are usually arthralgic in character; they are prone to develop suddenly, are rarely accompanied by effusions, and when severe, are most often due to embolic events. The complexion in the subacute cases tends to a *café-au-lait* tint, which is a point of diagnostic value to the trained eye. Clubbing of the fingers is very common, quite apart from the influence of possible old-standing valvular disease. The patients are often singularly optimistic concerning themselves. Libman lays stress upon areas of deep tenderness about the lower end of the sternum and the sterno-costal junctions. Albuminuria is very common, tending to increase with the progress of the disease, and doubtless associated with the focal glomerular nephritis to which reference has already been made.

Modes of Termination.—1. *Recovery.*—A rare event, yet one which certainly occurs at times, even when the diagnosis is beyond doubt.

2. *Death.*—Out of 149 cases studied by the writer, the recorded terminal events occurred in the following order of frequency: heart failure (66), coma (23), sudden death (19), uræmia (18), exhaustion (8), hyperpyrexia (2). Cases dying in coma were for the most part those in which cerebral embolism, with or without hæmorrhage, had taken place. Sudden death was due to perforation of a valve cusp, rupture of aneurysms in the sinus of Valsalva, perforation of the interventricular septum and cerebral hæmorrhage.

Diagnosis.—Evidence of endocarditis, the occurrence of multiple arterial embolism, and the isolation of micro-organisms from the blood stream: the co-existence of these three facts makes the diagnosis of septic endocarditis indubitable. But, as has already been remarked, the diagnosis may sometimes be made quite confidently in the absence of a positive blood culture in certain of the subacute cases. The most important point to establish is the presence of multiple arterial embolism. Seeing that the prognosis is so serious, it follows that a diagnosis of septic endocarditis should never

be made unless convincing evidence be forthcoming. In the differential diagnosis the following diseases call for consideration:

1. *Pneumonia.*—There may be considerable difficulty here, seeing that consolidation of the lung is usually present in pneumococcus infection of the endocardium. Care must be exercised, because hæmaturia and splenic enlargement in a case of pneumonia do not necessarily imply infarction. Nor does a positive blood culture in pneumonia necessarily mean endocarditis. But petechiæ, and the presence of emboli in arteries, in a case in which signs of valvular disease and a positive blood culture are present, justify a diagnosis of septic endocarditis.

2. *Typhoid fever.*—A positive Widal test with a leucopenia in a patient who has not previously suffered from the disease, or has not had prophylactic inoculation may be regarded as almost decisive in favour of typhoid fever; especially is this so if the agglutination titre is found to rise when the test is repeated after a few days. Typhoid infection of the endocardium is very rare.

3. *Rheumatic fever.*—The recurrence of acute rheumatism in a patient who has previously developed valvular disease often gives rise to considerable anxiety on account of the similarity which may exist between the symptoms present and those of septic infection of the endocardium. The rheumatic process may spread itself over several months, salicylates notwithstanding. These difficult cases usually occur in children between the ages of 10 to 16 years. Endocarditis is always present, and often there is pericarditis, or pleurisy, or both; though pericarditis is a common complication in rheumatic infection, it is very rare in septic endocarditis, resulting only from infarction or an aneurysm leaking into the pericardial sac. There may be considerable loss of flesh and marked anæmia. The form of the temperature chart rarely affords help. The facts which help to exclude septic endocarditis are the presence of nodules, or of chorea, and the absence of petechiæ, of hæmaturia, of enlarged spleen, and especially of micro-organisms in the blood stream.

4. *Peliosis rheumatica* may cause even greater difficulty, but the condition is uncommon. The association of fever, purpura, anæmia, albuminuria and joint pains in a case of old-standing aortic regurgitation under the writer's care naturally raised fear of infection of the damaged valve cusp. But the purpuric spots and the joint pains were bilateral and symmetrical, there were ecchymoses in addition to the petechiæ, there were effusions into the joints, and blood cultures yielded no growth.

5. *Malaria.*—The resemblance is but superficial, owing to the fact that in some cases of septic endocarditis the fever may be markedly intermittent, and rigors with heavy sweats may occur. The absence of malarial parasites in the blood and the absence of leucopenia are much against a diagnosis of malaria.

6. *Tuberculosis.*—General tuberculosis may be closely simulated by acute septic endocarditis with continued fever when the heart signs are equivocal. But there is leucopenia in general tuberculosis, a sterile blood stream (on repeated culture), and signs of embolism do not occur. Sometimes cases of septic endocarditis find their way into sanatoria for the treatment of phthisis, on the ground that they are cases of "phthisis without physical signs."

Prognosis.—As has already been stated, recovery occasionally takes place in the acute, and still less frequently in the subacute form of the disease. All the same, the diagnosis once definitely established, the outlook is of the gravest, treatment notwithstanding. That the patient is very little affected in general health, that he is extremely hopeful concerning his condition, that the state of the heart in itself gives no cause for concern, and that the number of micro-organisms per c.mm. of blood has fallen very considerably—none of these things should tempt the physician to abate anything from the serious view he takes of the case. Periods of improvement often occur, with or without special lines of treatment, but the fatal issue seems only to be delayed. It is very difficult to surmise the length of time the patient will live after the diagnosis is made. If there are already present the signs either of renal or of cardiac failure the end is not far off; weeks measure it. Otherwise, developments may proceed quite slowly, and the patient may live some months. But there remain to be reckoned with the various accidents attending upon the dissemination of the endocardial vegetations, or the ulceration of the valves, either of which accidents may bring about a speedy termination. Not seldom, when it seems certain that the course of the disease has been checked, death, more or less sudden, and due to some purely mechanical cause, cheats the physician and those who watch his efforts.

Treatment.—PROPHYLACTIC.—Reference has been made to the undoubted fact that the source of the infecting agent in most cases is the mouth or intestine. This suggests that special attention should be directed to these regions in all persons who are the subjects of valvular disease. Oral sepsis of all sorts should receive treatment. Dead teeth, crowned, or not, should be sacrificed. Septic tonsils should be removed. The condition of the intestinal tract should be investigated, and measures adopted to lower the content of streptococci if this appears high.

CURATIVE.—The general (non-specific) measures adopted in the treatment of all cases of septicæmia are applicable here: plenty of fresh air and light, good food frequently administered, and hæmatinic drugs for the anæmia. The writers consider that open-air treatment, as for cases of pulmonary tuberculosis, should be adopted whenever possible. The various measures that have from time to time been tried in order to inhibit the bacterial factor in the disease are the following:

Chemical antidotes.—"Blood antiseptics" have, as a rule, proved very disappointing in the history of the treatment of the disease. Quinine, mercury, arsenic (including salvarsan), carbolic acid, formalin, the sulphocarbolates and many others, whether administered by mouth, subcutaneously or intravenously, lead to no results worth recording. On the other hand, efforts at "sterilisatio magna" of the blood stream are not without immediate danger. The introduction of sulphonamides in the treatment of coccal infections naturally led to their use in this disease. The results have been disappointing; this is to be attributed to the fact that these drugs are not helpful in *S. viridans* infections. The supplementary use of heparin is still under trial.

Anti-sera.—As most cases of septic endocarditis are of streptococcal origin, it was hoped that the use of anti-streptococcus serum might lead to cure. The result of a good many trials has been very disappointing. The

experience of vaccine therapy in this disease is no more cheering than that of serum therapy.

X-rays have been employed and radium, both alone and in conjunction with chemotherapy. Results have been encouraging only in a few cases where the infection was grafted upon a congenital defect.

A. E. GOW.

CHRONIC OR SCLEROTIC ENDOCARDITIS

Chronic or sclerotic endocarditis is characterized by an increase of the connective tissue of the valve-segments and other parts, which subsequently contracts.

Ætiology and Pathology.—Chronic endocarditis may be (1) a sequel to the acute simple variety, and, in the opinion of some, occasionally to subacute bacterial endocarditis; or (2) primary, that is, of a slowly progressive nature from the outset.

The first, *i.e.* secondary chronic endocarditis, is the more common. It is more apt to occur in early life, most frequently between the ages of 10 and 20. The mitral valve is more often affected. The connective tissue tends to contract as time advances, leading to thickening and shortening of the valve-segments, resulting in incompetence; or to adhesions between the cusps, with consequent stenosis; or to incompetence and stenosis combined. In the case of the mitral valve, there may also be shortening and thickening of the chordæ tendineæ and apices of the papillary muscles. In the case of aortic incompetence, the affection may be due to rupture of a valve-segment or to perforation. There may be a deposition of lime-salts. Recurrent attacks of acute endocarditis are not uncommon.

Primary chronic endocarditis is more frequent in males, and in later life. There are two varieties. The first is of much the same nature as atheroma—primary chronic degenerative endocarditis. It is more often met with in the elderly. The causes are much the same as in the case of atheroma (see p. 1038). The aortic valve is much more commonly affected, where it is relatively frequent, but it is not rare in the case of the mitral valve. There are patches of thickening and degeneration, and there may be calcification of the valves. There may be atheroma of the aorta, or of the coronary arteries, or general atheroma. The second variety is the result of syphilis, and generally commences in middle-life. The disease-process extends to the cusps of the aortic valve, resulting in incompetence, or, in the opinion of a few, rarely to absolute stenosis; and in the opinion of some, rarely to the base of the aortic cusp of the mitral valve, with consequent incompetence.

It may here be noted that fœtal endocarditis is usually of the chronic or sclerotic form.

Symptoms. Chronic or sclerotic endocarditis produces no symptoms until such structural changes have taken place in a valve as to cause stenosis, or incompetence, or both combined.

CHRONIC VALVULAR DISEASE

Definition.—By chronic valvular disease is meant a chronic affection of the cusps of the cardiac valves, or of the orifices, or both. Not only may

the orifices and cusps be affected, however, but also the chordæ tendineæ and the musculi papillares. Whatever the nature and form of the valvular affection, it gives rise to stenosis or narrowing, which results in obstruction to the flow of blood; or to incompetence, which allows of regurgitation; or frequently to both of these together. Along with organic valvular disease there are often coincident changes in the cardiac musculature, the coronary arteries, or the aorta.

The Relative Proportion and the Combinations of the Different Valvular Diseases.—It should be noted that not infrequently more than one valve is involved at the same time, especially in the case of rheumatic valvular disease.

The mitral is the valve most commonly affected, and incompetence of this valve is more frequent than stenosis. When mitral incompetence results from a previous attack of acute endocarditis, there is usually some degree of stenosis as well; when it is of the *relative* variety, it is often associated with tricuspid incompetence. Pure mitral stenosis is nearly always infrequent; in the process of thickening and contraction there is some degree of incompetence. Aortic regurgitation is very common; a greater or less degree of stenosis, however, not infrequently accompanies the incompetence. Pure aortic stenosis, on the other hand, is one of the rarest of valvular affections. There is usually also incompetence of the valve, generally at most of moderate degree. Disease of the pulmonary valve is comparatively rare, and is usually of congenital origin. Pulmonary stenosis is one of the most frequent forms of congenital heart disease; as an acquired condition, it is very rare. Pulmonary incompetence is the rarest of valvular diseases. Tricuspid incompetence is the most common form of right-sided valvular affections. In the vast majority of cases it is of the *relative* variety, in which case it is a common result of mitral disease. Tricuspid incompetence is rarely primary, and then stenosis is usually present with it and it may also be mitral or aortic disease. When tricuspid incompetence occurs alone it is in all probability congenital. Tricuspid stenosis is comparatively rare, but not so rare as was formerly supposed; the acquired form is usually associated with mitral stenosis, and there may also be aortic valvular disease.

In chronic valvular disease due to acute or subacute rheumatism, the following is the order of frequency: mitral disease alone; mitral and aortic disease; aortic disease alone; mitral and tricuspid disease.

Ætiology.—Chronic valvular disease may be of congenital origin (*vide* Congenital Heart Disease); or the result of a previous attack of acute simple endocarditis and, in the opinion of some, of subacute bacterial endocarditis; or of primary chronic degenerative endocarditis; or, in the case of the aortic valve and, in the opinion of some, rarely of the mitral valve, of syphilis; or new-growths; or traumatism; or functional. This does not include *relative* incompetence of a valve.

When chronic valvular disease is the result of a previous attack of acute endocarditis, it is more apt to occur in early life; when due to primary chronic endocarditis of a degenerative nature, in later life; while, in the case of syphilis, the morbid affection usually commences in middle life. Neoplasms may arise from the walls of the heart or from the valves. They rarely cause obstruction. A traumatic lesion of a cusp or of the chordæ tendineæ, the result of excessive physical exertion, may cause incompetence, or stenosis of

a valve, and is of much more common occurrence in the case of the aortic than the mitral valve. It rarely takes place, however, in the absence of pre-existing disease of the valve.

In *relative* incompetence of a valve the cusps themselves are healthy. This is more common on the right than on the left side of the heart, and is not nearly so frequent in aortic as in mitral disease. In the case of the auriculo-ventricular valves the condition may be brought about by: (1) Dilatation of the cavity of the ventricle; (2) enlargement of the orifice on account of relaxation of the surrounding muscular structures; the tonicity of the muscular ring is impaired, and the cusps do not completely come together; (3) both combined; (4) shrinkage or stretching of the musculi papillares or chordæ tendineæ as a result of disease. In the case of the semilunar valves, it is the result of dilatation of the aortic ring, or of the pulmonary orifice, as the case may be.

Pathology.—See Chronic or Sclerotic Endocarditis, and Syphilitic Mesaortitis.

Effects of Valvular Disease upon the Walls of the Heart and other Organs.—It can be readily understood that a valvular lesion is a mechanical impediment to the heart muscle in its work. The heart, however, possesses the faculty of adapting itself to this and thus maintaining an efficient circulation; that is, what is called *compensation* is established. This is brought about by an increase in the thickness of the muscular walls and, in some cases, also by an increase in the capacity of the cavity of one or more of the chambers of the heart, *i.e.* compensatory hypertrophy and compensatory dilatation respectively. It should be clearly understood that compensatory dilatation is different from the dilatation which is the result of cardiac, *i.e.* muscular failure.

When compensation is such that the heart is fully up to the normal, there is what is termed complete compensation. Comparatively rarely is this the case, *i.e.* there is usually a diminution in the reserve force and, it may be, of the rest force of the heart; and in any case such is apt to occur sooner or later. This is called 'decompensation,' or failure or loss of compensation. Some, however, limit at least the latter term to cardiac failure of 'moderate' or more severe degree (see p. 857).

In the case of stenosis of a valve, as the process of narrowing of the orifice is usually slow, the muscular wall of the chamber immediately behind the orifice hypertrophies, which enables it to overcome the obstruction; in other words, compensatory hypertrophy takes place. If this is complete, a normal amount of blood is propelled through the smaller valve aperture.

In the case of valvular incompetence, the cavity immediately behind the orifice has to accommodate the regurgitant stream of blood in addition to that which arrives in the normal manner, so that an increase in the capacity of the chamber is necessary, *i.e.* compensatory dilatation occurs. Again, a larger amount of blood than normal must be propelled with each systole of the chamber in order to make up for that which regurgitates, with resultant hypertrophy of the muscular wall, *i.e.* compensatory hypertrophy takes place. If this is complete, the circulation receives the normal supply of blood.

The muscular power of a hypertrophied chamber tends to fail sooner or later, *i.e.* cardiac failure and secondary dilatation occur. In this event, there is a diminished blood supply in front of the orifice and an increase in the

amount of blood behind it. A cavity dilated in this manner is placed at a disadvantage in contraction. In the case of a ventricle, there may be stretching of the mitral or tricuspid orifice, with *relative* or functional incompetence of either valve.

Passing to the consideration of the different valvular lesions:

In aortic valvular disease, the strain falls on the left ventricle. In stenosis, the chamber hypertrophies, it may be to a considerable degree. A normal amount of blood may be propelled into the aorta. Cardiac failure and consequent dilatation of the left ventricle and, it may be, *relative* mitral incompetence may supervene, in which case there may be the same subsequent events as in mitral disease. In aortic incompetence, there is both compensatory dilatation and hypertrophy of the left ventricle (Fig. 37), which may be even very marked—the so-called *cor bovinum*—especially if there is also mitral incompetence. If compensation is complete, the latter is propor-

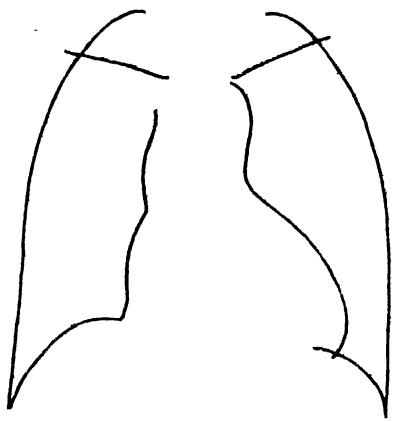

FIG. 37.—Orthodiagram from a case of aortic incompetence, of rheumatic origin, showing enlargement of the left ventricle.

tionate to the former. Secondary dilatation may supervene, with, it may be, *relative* or functional mitral incompetence and its subsequent events.

In mitral stenosis, the strain falls mainly on the left auricle and, still more so, on the right ventricle. The former chamber dilates and, to a certain extent, hypertrophies. The right ventricle hypertrophies, it may be markedly so. The pressure in the pulmonary circulation is raised, there is apt to be chronic venous congestion and œdema of the lungs, and the pulmonary artery and its branches may become dilated and even atheromatous. Later, the right ventricle dilates, and *relative* or functional tricuspid incompetence, dilatation and hypertrophy of the right auricle, and systemic chronic venous congestion may supervene. Occasionally when the wall of the left auricle is diseased, that chamber dilates to aneurysmal proportions, extending to the right as far as the chest-wall. On X-ray examination, enlargement of the left auricle, the pulmonary artery and the right ventricle can usually be made out. The left auricle projects backwards and to the right, and the

infundibular part of the right ventricle and the pulmonary artery project above the left ventricle on the left border of the heart (Fig. 38). In cases in which auricular fibrillation with cardiac failure is present, the right auricle

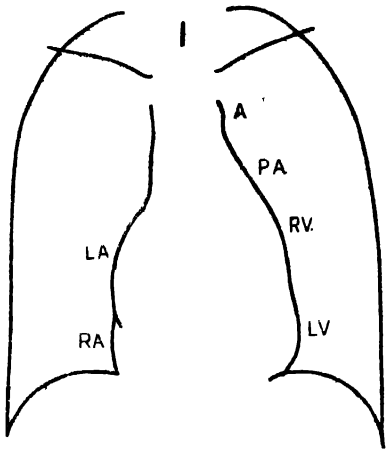

FIG. 38.—Orthodiagram from a case of mitral stenosis, showing enlargement of the left auricle, which projects to the right, and enlargement of the pulmonary artery and infundibular part of the right ventricle on the left border of the heart. A., aorta; P.A., pulmonary artery; R.V., infundibular part of the right ventricle; L.V., left ventricle; L.A., left auricle; R.A., right auricle.

becomes increasingly enlarged (Fig. 39). In uncomplicated stenosis, the left ventricle does not hypertrophy; indeed, the quantity of blood passing from the left auricle to the left ventricle may be less than normal, and the chamber

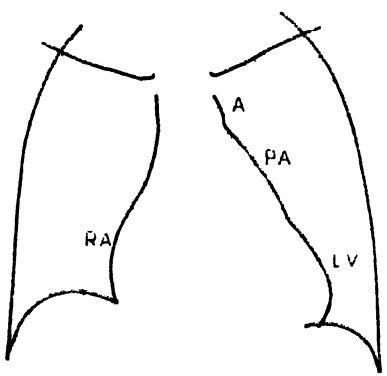

FIG. 39.—Orthodiagram from a case of mitral stenosis and auricular fibrillation with cardiac failure.

may be rather atrophied. If, however, there is also mitral incompetence, there is left ventricular dilatation and hypertrophy. In mitral incompetence, in accordance with the principles explained above, the left ventricle under-

goes both compensatory dilatation and hypertrophy. Secondary dilatation may occur. There may be dilatation and hypertrophy of the left auricle, and the subsequent events resemble those in mitral stenosis.

Lesions of the right side of the heart produce corresponding results to those of the left. In pulmonary stenosis, the right ventricle hypertrophies, it may be in a marked degree, and later may dilate. In pulmonary incompetence, compensatory dilatation and hypertrophy of the right ventricle occur, and it may be secondary dilatation. In tricuspid stenosis, there is dilatation and, to a certain extent, hypertrophy of the right auricle; while in tricuspid incompetence, compensatory dilatation and hypertrophy of the right ventricle take place, and secondary dilatation may occur.

Valvular disease of the right side of the heart is apt to cause systemic venous congestion.

Symptoms. See cardiac failure; the different valvular diseases; and syphilitic aortitis.

Aortic Stenosis

Aortic stenosis may be absolute or relative. In absolute stenosis the orifice is less than its normal size, while in relative stenosis the size is normal, but dilatation of the aorta just above the valve is present.

Ætiology.—Absolute stenosis is almost always the result of an antecedent attack of acute endocarditis, in which case there is usually incompetence, generally, at the most, of moderate degree, and not rarely the mitral valve is also affected; or primary chronic degenerative endocarditis. The first is the commonest cause in young adults, and the second in the elderly. It is rarely of congenital origin and, in the opinion of a few, due to syphilis.

Relative stenosis due to general dilatation of the aorta just above the valve may be caused by atheroma or syphilis.

Symptoms.—The symptoms are usually very delayed and, indeed, the condition may be latent all through life—even more than in the case of mitral incompetence, but when they do occur they appear more rapidly. They are those of aortic incompetence excepting that a sensation of beating or throbbing in the head or elsewhere is uncommon; those of cerebral anæmia are, in my opinion, less frequent; anæmia is rare; pain and angina occur less often; and sudden death is not so likely.

In uncomplicated stenosis, the pulse may not show any appreciable abnormal features. If, however, of considerable or more degree, it is of smaller amplitude, the upstroke is slow, and gradual and oblique, and the pulse is well sustained. It may be anacrotic, or of the bisferiens type. In the case of the former, the tidal wave may be more forcible than the percussion wave, and as a result the latter part appears merely as an indentation in a slow slanting upstroke, the apex of which is formed by the tidal wave. In the latter the tidal wave may be felt separately from the primary impact—that is to say, the summit is bifurcate due to the predicrotic fall being followed by a rise equal to or above that of the percussion wave. The blood pressure tends to be rather subnormal, with the diastolic relatively high. When the lesion is due to primary chronic degenerative endocarditis, hypertension may be present; and the vessel wall may be thickened and

tortuous. Almost always there are evidence of hypertrophy of the left ventricle (see p. 955), it may be of considerable degree; and the outthrust of the apex-beat may be even slower and longer than in the case of hypertrophy—a 'slow heave,' which is sustained. The area of cardiac impairment is correspondingly increased.

A thrill, systolic in time, is usually palpable at the base, generally best felt in the aortic area, and as a rule rough. There is a systolic murmur at the base, with its point of maximum intensity usually in the aortic area, usually harsh but it may be musical or blowing. The murmur is often loud and, indeed, cases have been recorded in which it was heard even several feet away from the patient. The direction of selective conduction is upwards along the vessels of the neck, but if the murmur is loud it may be audible all over the front of the chest and even at the back, in which case it is most evident at the level of the fourth vertebra, close to the left border of the spinal column. The second sound in the aortic area varies considerably in loudness, largely due to the nature of the lesion and the presence or absence of arterial disease. Thus, the fusion of the cusps may be such as not to allow the necessary apposition, so that the second sound is diminished or practically absent. In hypertension and atheroma, on the other hand, the sound is apt to be increased.

Signs of dilatation of the aorta are sometimes also present.

The physical signs of *relative* mitral incompetence may supervene.

Diagnosis.—For the diagnosis of syphilitic aortitis, see pp. 978, 979.

It is necessary to point out that it is not justifiable to make a diagnosis of aortic stenosis from the mere presence of a systolic murmur over the aortic area, additional evidence being required.

A diagnosis of aortic stenosis can readily be made when the characteristic pulse, evidence of left ventricular hypertrophy, an aortic systolic thrill and murmur, especially if the latter is loud and harsh, with the direction of selective propagation upwards along the vessels of the neck, and a diminished or absent second sound are present. When, however, only one or few of these features are present, difficulty with regard to the diagnosis may easily arise. An anacrotic pulse is characteristic, but not pathognomonic; nevertheless, it is of greater diagnostic value than pulsus bisferiens. While the presence of a thrill is a valuable diagnostic sign, it may also be found in circumscribed aneurysm of the aorta. A systolic murmur with the direction of selective propagation upwards along the vessels of the neck is at least strongly presumptive, and, in the opinion of some, is almost sufficient evidence. Before arriving at a diagnosis of absolute stenosis, unless a typical pulse is present, X-ray examination for dilatation of the aorta is necessary.

Certain conditions must be excluded in considering the diagnosis of aortic stenosis. Among these are bruits due to anæmia; cardio-respiratory or cardio-pulmonary murmurs; those due to excitation of the cardiac action, for example, in thyrotoxicosis; mere roughness or stiffness of the aortic cusps; general dilatation (diffuse aneurysm) of the aorta just above the valve; circumscribed aneurysm; pulmonary stenosis; patency of the interventricular septum; and pressure upon the aorta by a mediastinal tumour in which no definite pulsation can be detected.

The distinguishing features of cardio-respiratory murmurs are discussed on p. 939. In general dilatation of the aorta just above the valve, the murmur

may sometimes be heard over the vessels of the neck, but occasionally the area of impairment at the level of the second and third intercostal cartilages extends farther to the right than the normal limit, the second sound is usually accentuated and may also be ringing, and audible over a much wider area, and there may be pulsation in the supra-manubrial notch. In a circumscribed aneurysm there may be a systolic murmur and thrill, but as a rule there is little difficulty in diagnosis. It is unnecessary to point out the value of X-ray examination in the diagnosis of both forms of dilatation of the aorta. The differential diagnosis from pulmonary stenosis is dealt with on p. 941.

Prognosis.—The prognosis of aortic stenosis depends mainly on the ætiology, the degree of the lesion, whether it is stationary or progressive, and the condition of the myocardium, the aorta and the coronary arteries. Some authorities are of opinion that when the affection is due to antecedent acute endocarditis, the outlook is even more favourable than in mitral regurgitation. When it is the result of primary chronic endocarditis, the prognosis is less favourable, as the lesion is more likely to be progressive, and to be associated with chronic myocardial disease, and atheroma of the aorta and even of the coronary arteries. If syphilis is responsible for the lesion, the outlook is much worse.

Treatment.—See p. 944.

Aortic Incompetence

Ætiology.—Aortic incompetence is more commonly found in middle or later life, and in males. There are three main causes: (1) A previous attack of acute endocarditis, in which case some degree of stenosis is not uncommon, and the mitral valve is often affected. This is the commonest cause of the condition in young adults. (2) Syphilitic mesaortitis. This usually commences in middle life. The valvular incompetence may be due to the disease-process spreading to the cusps; or to dilatation of the aortic ring—relative incompetence; or to both. (3) Primary chronic degenerative endocarditis, more particularly when the affection occurs in the elderly. Relative incompetence is sometimes also the result of atheroma, persistent hypertension, and, in the opinion of some, rarely in severe anæmia. Aortic incompetence is the most frequent chronic valvular affection due to injury, and may follow sudden physical overstrain, causing a rupture of a valve-segment. The condition is extremely rarely of congenital origin.

Symptoms.—The reader is also referred to Syphilitic Aortitis.

In not a small proportion of cases the malady is latent for many years. When symptoms do occur they tend to do so less gradually than in the case of mitral disease unless in the latter there is associated auricular fibrillation. Shortness of breath is possibly the most common symptom. The patient may complain of consciousness of the action of the heart, or of a sensation of beating or throbbing in the head, the neck, or elsewhere. Symptoms due to cerebral anæmia, including giddiness and faintness with change of posture, are relatively frequent, and probably more so than in any other form of heart disease. Not uncommonly the patient is pallid, and he may have an anxious expression; later, when relative incompetence of the mitral valve has become established, the facies may resemble that which is characteristic of mitral cases. In some there is pronounced anæmia. Præcordial pain and angina

pectoris occur more often than in mitral disease, especially if the coronary arteries are implicated. Left ventricular failure may develop (see p. 857). Right-sided failure (see p. 857) may supervene, but œdema is less frequent than in mitral and chronic myocardial disease, and widespread œdema is relatively exceptional.

Embolism and auricular fibrillation are less frequent than in mitral disease, while sudden death occurs more often than in any other form of valvular disease.

In uncomplicated aortic incompetence, the typical pulse is very characteristic, and is called the collapsing, the water-hammer, or Corrigan's pulse. Its character may be intensified by grasping the wrist and raising the arm above the head, and this method of examination should always be employed

FIG. 40.—Sphygmogram from a case of aortic incompetence.

in suspected aortic regurgitation. The typical pulse is of great amplitude, the upstroke is rapid and more vertical, and the fall is sudden. The tidal wave may be considerable, but is maintained only for a short period, the dicrotic notch falls low on the downstroke, while the dicrotic wave may be well marked, small, or altogether absent (Fig. 40). The artery is empty between the beats. The systolic blood pressure is variable but is usually increased, while the diastolic is diminished and may be very low, with resultant increase in the pulse-pressure, which may be great. The systolic blood pressure in the femoral artery is higher than in the brachial. When, in addition to incompetence, absolute stenosis is present, the characteristic pulse and blood pressure of the former will be modified by the latter condi-

FIG. 41.—Sphygmogram from a case of aortic stenosis and incompetence. The characteristic pulse of the latter condition is modified by the presence of stenosis.

tion (Fig. 41); this is of great diagnostic importance. A characteristic feature of aortic incompetence is exaggerated pulsation of the arteries. This may be especially noted in the carotid, temporal and brachial arteries, and may be evident in the abdominal aorta, in the suprasternal notch, and elsewhere. Increased pulsation of the retinal arteries is sometimes to be noted with the ophthalmoscope. With light pressure of the stethoscope over the larger arteries, *e.g.* the femoral, the brachial and the carotid, a sharp clear sound during systole—the so-called pistol shot sound—may be audible, while with moderate pressure, a double murmur is sometimes to be noted—the Duroziez's sign. The phenomenon of the capillary pulse may be observed, and visible pulsation in the superficial veins, especially in the veins of the back of the hand, when hanging down, is rarely to be noted. In the opinion of some writers, pulsation over the upper part of the præcordium, and in the

second and third right intercostal spaces, is occasionally to be noted, even in the absence of dilatation of the aorta.

There is evidence of hypertrophy of the left ventricle, which may even be very marked—the so-called *cor bovinum*, especially if there is also mitral incompetence (see p. 955).

A diastolic murmur is audible. It usually commences with the second sound, which it may replace or merely accompany, or sometimes immediately after it, and continues for a variable period, generally the greater part, during the long pause. Its point of maximum intensity is variable. While typically over the inner end of the second right intercostal cartilage, in the majority of cases it is elsewhere: often over the sternum, usually anywhere between the level of the second rib to the fourth space, but occasionally somewhat below this; or, probably less frequently, along the left border of the sternum, from the level of the second to the fourth intercostal spaces, but generally in the third and fourth. Rarely it is loudest in the neighbourhood of the xiphisternum or the apex. The murmur is often heard over a wide area. Its selective propagation is downwards. It is diminuendo, and usually blowing but occasionally musical. There is occasionally a diastolic thrill, its point of maximum intensity being the same as that of the murmur. An aortic systolic murmur is often, if not usually, present, due either to dilatation of the aorta or to absolute stenosis. Not infrequently a murmur during diastole is audible at the apex (Flint's murmur), and in a certain proportion of these also a presystolic thrill.

In *relative* incompetence, the second sound is usually accentuated and this may sometimes be determined.

For the results of X-ray examination, see p. 928 and Fig. 37, and pp. 977, 978 and Fig. 44.

Later, the physical signs of relative mitral incompetence may be present.

Diagnosis.—For the diagnosis of syphilitic aortitis see pp. 978, 979.

There is little or no difficulty in recognising aortic incompetence in the great majority of cases. The character of the pulse and blood pressure, exaggerated pulsation of the arteries and the phenomenon of the capillary pulse, signs of hypertrophy of the left ventricle, a diastolic murmur and, it may be, a thrill, presenting the features described, furnish a clinical picture with regard to the diagnosis of which there should be no mistake. It is to be noted that the arterial signs, in varying number, are sometimes met with in other conditions, for example, thyrotoxicosis. In slight incompetence, none of these signs may be present, there may be little or no evidence of left ventricular hypertrophy, and a diastolic murmur may be difficult to hear and inconstant. It is, therefore, very advisable that auscultation should be conducted under the quietest conditions possible, with the patient in various postures, and including during holding the breath after a full expiration.

In the differential diagnosis from *relative* incompetence the results of X-ray examination are valuable. When in aortic incompetence there is also a systolic bruit, if such is due to stenosis, the characteristic pulse of the former will be modified by the latter condition.

When the point of maximum intensity of the murmur is in the pulmonary area the condition may be mistaken for pulmonary incompetence. In the latter, the symptoms are principally those of right-sided failure; there is an

absence of the characteristic pulse and blood pressure, of exaggerated pulsation of the arteries, and of capillary pulsation; and there is evidence of hypertrophy of the right, and not of the left, ventricle. In addition, pulmonary incompetence is generally due to dilatation of the pulmonary artery, *i.e.* *relative* incompetence, in which event there is evidence of the causal condition.

When in mitral stenosis there is a diastolic murmur in the pulmonary area, it may be difficult to determine whether this is indicative of slight aortic incompetence or is a Graham Steele's murmur, but it may be noted that the latter is relatively rare.

In cases in which there is a diastolic bruit with its point of maximum intensity at or near the apex-beat, the differential diagnosis between aortic incompetence and mitral stenosis arises. This is discussed on p. 938.

A venous hum in the neck transmitted downwards to over the sternum, even its lower part, a patent ductus arteriosus, and an arterio-venous aneurysm may be mistaken for aortic incompetence. In the case of each, there is a continuous murmur during systole and diastole, frequently with a systolic accentuation. The differential diagnosis is not difficult.

When in addition to aortic incompetence there is stenosis, the characteristic pulse and blood pressure of the former will be modified by the latter condition (see Fig. 41).

Prognosis.—The prognosis of aortic incompetence is usually serious. Sudden death is more frequent than in any other form of chronic valvular disease, and may occur even when there are few or no indications of cardiac failure.

In attempting to form a prognosis, the ætiology, the degree of the lesion, whether it is stationary or progressive, the condition of the myocardium, the aorta and the coronary arteries, and whether the patient is subject to syncopal attacks and attacks of angina pectoris should be considered. When the lesion is the result of a previous attack of acute endocarditis, the prognosis is much more favourable than when due to other causes; indeed, if there be no indications of cardiac failure, and if the character of the pulse, the pulse-pressure, and the size of the heart, exhibit little or no alteration, the patient may live to an advanced age. When it is due to primary chronic degenerative endocarditis, the prognosis is less favourable, as the lesion is more likely to be progressive, and to be associated with chronic myocardial disease and atheroma of the coronary arteries. If syphilis is responsible for the lesion, the outlook is much worse. When aortic incompetence is the result of rupture of a cusp, the prognosis is still more grave, and a fatal termination may rapidly supervene. As regards the degree of the lesion, the degree of modification of the pulse and of the blood pressure, and the size of the heart are of special significance. Attacks of angina pectoris are usually of grave omen.

Treatment. See p. 944.

Mitral Stenosis

Ætiology.—Mitral stenosis commences much more commonly in early life, and is much more frequent in females than in males. In the great majority of cases it is the result of an antecedent attack of acute endocarditis of rheumatic origin. Some are of opinion that it is always so. I do not share this view. It sometimes originates in adults as a result of primary chronic de-

generative endocarditis, not infrequently in association with chronic renal disease. In others the ætiology is obscure.

Pathology.—In mitral stenosis the commonest type of lesion is for the cusps to be united by their margins; but it may be situated elsewhere, as, for example, at the level of the auriculo-ventricular ring. When the lesion consists of a union of the margins of the cusps, two well-marked types of stenosis may result—(1) The 'funnel-shaped mitral,' which is more common in childhood; and (2) the 'button-hole mitral,' which is by far the more common in adults and persons of advanced years.

In the former, the cusps are simply adherent and form a funnel-shaped membrane which projects downwards into the left ventricle, the wide mouth of the funnel being situated at the ring, and the smaller end being drawn down towards the apex of the heart, by shortening of the chordæ tendineæ and papillary muscles. In the case of button-hole stenosis, the cusps are also shortened and form a diaphragm, perforated by a narrow slit-like aperture, which almost closes the orifice. A combined form, that is, a funnel having a narrow slit at its lower end instead of a circular aperture, has also been described.

Symptoms.—Not infrequently for many years there may be only shortness of breath on severe exertion. In other cases, subjective symptoms, most commonly dyspnœa and next fatigue, occur on less exertion. The most frequent symptoms are respiratory. In addition to shortness of breath on effort, cough is relatively frequent; the patient is liable to such affections as bronchitis and broncho-pneumonia; and hæmoptysis is not uncommon. There may be physical signs of chronic venous congestion or œdema of the bases or over a wider area of the lungs. Right-sided failure is apt to supervene. There may be a persistent dusky flush over the cheeks; later, lividity of the lips, cheeks, tips of the ears, and the finger nails; and still later, clubbing of the fingers. Cerebral symptoms are not uncommon. Paroxysmal dyspnœa and acute pulmonary œdema are rarely met with in marked stenosis with sudden tachycardia. Angina pectoris is rare. Embolism is of much more frequent occurrence in mitral stenosis than in any other variety of valvular disease. Pressure on the left recurrent laryngeal nerve, resulting in paralysis of the vocal cord, is rarely met with.

The supervention of auricular fibrillation, with its usual consequences (see pp. 897, 899), is relatively frequent. Acute or subacute endocarditis is liable to occur. The fatal termination is usually the result of gradually increasing right-sided cardiac failure. Sudden death is rare.

In uncomplicated mitral stenosis the following may be present. In a fair proportion of cases the pulse is small, the upstroke being short and soon attaining its maximum, the pulse-wave is long, and dicrotism is absent. If there is auricular fibrillation, there is complete irregularity of rhythm. Sometimes the systolic blood pressure is rather subnormal, and the diastolic may be rather raised, so that the pulse is full between the beats. The apex-beat may be in the normal position, or rather displaced to the left. It may be normal in character, or sudden and short, the latter being somewhat characteristic.

There may be pulsation in the pulmonary area, synchronous with the apex-beat, due to enlargement of the pulmonary artery and the conus arteriosus. There may be evidence of enlargement of the left auricle and

of the right ventricle (see pp. 955 and 956). The first sound at the apex is short and accentuated. The second sound in the pulmonary area is not infrequently accentuated and may be reduplicated.

Examination for the characteristic murmur and thrill should be conducted with the patient in the upright position, and lying on his back and on the left side, both before and after exertion, or the inhalation of amyl nitrite. The murmur has its point of maximum intensity at the apex or rather nearer the parasternal line. Its area is often very limited—which should be noted, as this sometimes results in the lesion not being recognised—but it may be fairly wide and occasionally even as high as the pulmonary artery. It is usually of a low pitch and rumbling character, but occasionally is of higher pitch and blowing. The murmur is at any time from early in diastole, *i.e.* separate from but quickly following the second sound, to right up to the next first sound. The portion (or portions) of this period occupied by the murmur (or murmurs) depends upon the velocity of the blood through the mitral orifice. This in turn depends upon the cardiac rate and the degree of the stenosis. The more rapid the cardiac rate and consequent shortening of the diastolic period, the greater the rate of flow required for a given quantity of blood to pass through the mitral orifice; and, in like manner, the smaller the orifice. In normal rhythm, if the cardiac rate is slow, the murmur is short. It is generally presystolic, in which case it increases in loudness, *i.e.* is crescendo, right up to the first sound; but it may be early diastolic, in which event it is diminuendo. In moderate tachycardia, there is usually an early or early and mid-diastolic, and a presystolic murmur, with an interval between. If the rate is very rapid, the whole of the diastole is occupied, with presystolic accentuation. In auricular fibrillation, if the cardiac rate is slow, the murmur is short and occurs early in diastole. In moderate tachycardia, in the longer cycles it occupies part of diastole and in the shorter ones the whole of it, with presystolic accentuation. If the rate is very rapid, it fills the whole of diastole, with presystolic accentuation. The portion of the diastolic period occupied by the murmur (or murmurs), will, in like manner, depend upon the degree of the stenosis, whether slight, moderate, or severe. A thrill is often present. Its point of maximum intensity is the same as that of the murmur, but its area tends to be more limited. The portion (or portions) of the diastolic period is also the same. The thrill increases in intensity up to the first sound, and there may be a sensation communicated to the hand resembling that produced by the purring of a cat. Sometimes there is a diastolic bruit, with its point of maximum intensity in the pulmonary area, due to relative incompetence of the pulmonary valve (see p. 942); it is called a Graham Steele's murmur.

If, as is usually the case, mitral incompetence is also present, the physical signs of both lesions will be evident.

For the results of electro-cardiographic examination, see p. 1007.

When cardiac failure occurs, the physical signs of dilatation (see p. 956) and of relative tricuspid incompetence may be present.

Diagnosis.—A diagnosis may be made from the characteristic physical signs. The results of X-ray and electro-cardiographic examinations, especially the former, are also valuable. Respecting the physical signs, the murmur and the thrill, particularly the former, are naturally the most important. The latter should be distinguished from a mere vibration of the chest-wall, which

may be occasioned by a forcibly acting heart when the ribs are rigid. In this case, by separating the fingers and placing them in the intercostal spaces the osseous vibrations are not felt. A short and accentuated first sound at the apex and an accentuation of the pulmonary second sound are more frequently met with in excitation of the cardiac action than in mitral stenosis. Even in the absence of a murmur and thrill, a combination of a history of acute or subacute rheumatism, subjective symptoms on physical exertion, and, excluding excitation of the cardiac action, an apex-beat, first sound and pulmonary second sound of the character described should arouse suspicion.

In cases in which there is a diastolic bruit with its point of maximum intensity at or near the apex-beat, the differential diagnosis between mitral stenosis and aortic incompetence may arise. In the latter the murmur commences with the second sound or immediately after it; it generally continues during the greater part or the whole of diastole; is diminuendo; there is never presystolic accentuation; the murmur is usually blowing and of a higher pitch instead of rumbling and low pitch; it is less localised; and is not louder on lying down. The first sound is not short and accentuated. In addition, the character of the pulse and blood pressure, whether there is exaggerated pulsation of the arteries and capillary pulsation, and whether there is evidence of hypertrophy of the left or right ventricle should be taken into consideration. It should be remembered that both lesions may be present at the same time. In this event, the characteristic pulse of aortic incompetence will be modified by the mitral stenosis.

A murmur during diastole at the apex may be due to what is sometimes called *relative* or functional mitral stenosis the result of considerable dilatation of the left ventricle, such as may occur in aortic incompetence, rheumatic myocarditis and hypertension; in the case of aortic incompetence it is known as a Flint's murmur. The murmur has the same features as in organic mitral stenosis, but usually it is not so loud and vibratory, or so constant, and a thrill is less common. In aortic incompetence, a previous history of acute or subacute rheumatism is in favour of organic mitral stenosis.

Prognosis.—Mitral stenosis ranks after aortic incompetence in gravity among the chronic valvular lesions, and the prognosis is much less favourable than in the case of mitral incompetence.

There is apparently a tendency for mitral stenosis to be progressive, pulmonary complications are frequent, and embolism is relatively frequent. When the lesion occurs in the early years of life, physical and mental development are apt to be retarded, and the patient is liable to fresh attacks of rheumatic valvulitis. The prognosis depends upon, among other things, the degree of stenosis, which when considerable is almost invariably accompanied by incompetence. The supervention of a diastolic murmur marks a downward grade. Sudden death is of rare occurrence, a fatal termination being usually the result of gradual cardiac failure, which in most cases is associated with the supervention of auricular fibrillation.

Treatment.—See p. 944.

Mitral Incompetence

Mitral regurgitation may be organic, or *relative* or functional.

Ætiology.—When organic, by far the most common cause is a previous

attack of acute endocarditis, but sometimes it is due to primary chronic endocarditis. Trauma and, in the opinion of some, syphilis are rare causes. In the case of the former, there is usually a rupture of a chorda tendinea or of a cusp. *Relative* incompetence is a somewhat common cause of mitral regurgitation. It may be due to acute febrile affections, acute myocarditis, chronic myocardial disease, aortic valvular disease, hypertension, chronic Bright's disease, anæmias, and primary cardiac strain.

Symptoms.—In organic mitral incompetence, occasionally there is an absence of subjective symptoms throughout the whole course. When symptoms are present, the clinical picture resembles that of mitral stenosis, but usually the degree of failure is less, and hæmoptysis, embolism, and perhaps auricular fibrillation are less common.

In uncomplicated cases, the pulse may exhibit some diminution in volume and the blood pressure may be rather subnormal. If there is auricular fibrillation, there is complete irregularity of rhythm. There is usually evidence of hypertrophy of the left ventricle, and it may be of enlargement of the right ventricle and the left auricle (see pp. 955, 956). Occasionally there is a systolic thrill at the apex, generally not rough. There is a systolic murmur, with its point of maximum intensity at the apex-beat. Almost always it accompanies the first sound and may also follow it, while rarely only the latter. It is usually blowing, occasionally musical, and less frequently harsh. Occasionally its loudness varies from cycle to cycle. The louder the murmur the larger the area of propagation. If loud, it may be audible over a wide area of the left chest, including posteriorly. The direction of selective propagation is towards the axilla and the angle of the scapula. It is generally heard as far as the former. The second sound in the pulmonary area may be accentuated and occasionally reduplicated.

When cardiac failure supervenes, the apex-beat may become more diffuse and less forcible, the transverse area of cardiac impairment may increase, both to the left and right, and the physical signs of tricuspid incompetence may be present.

Diagnosis.—It should be clearly understood that a systolic adventitious sound audible over the apex of the heart is not necessarily indicative of mitral incompetence, for such may be due to other causes, which should be excluded. These include cardio-respiratory or cardio-pulmonary murmurs, those due to excitation of the cardiac action, such as in thyrotoxicosis, the propagation of a systolic murmur from the base or elsewhere, and exocardial sounds due to pericardial friction, or to a local pleurisy at or near the apex causing friction.

The following are in favour of mitral incompetence, though not necessarily indicative of it: (1) Enlargement of the heart, and it may be hypertrophy—unless it pre-existed. (2) The relative constancy of the murmur, if of a harsh character, if audible over a large area, the direction of its selective propagation, and an absence of variation with the phases of respiration. (3) The existence of a thrill. (4) Accentuation of the second sound in the pulmonary area. (5) A history of rheumatism.

Cardio-respiratory murmurs vary with the different phases of respiration—such as increasing during inspiration and diminishing during expiration, or disappearing on holding the breath after full inspiration or expiration—and are usually short.

In *relative* mitral incompetence, there is an absence of evidence of left ventricular hypertrophy—unless this pre-existed; the size of the heart is generally less—in the absence of other factors; the loudness of the murmur is more affected by the adoption of the recumbent posture and by exercise; and there is often no accentuation of the pulmonary second sound. The opposite is in favour of organic mitral incompetence, as is also a history of rheumatism and the presence of mitral stenosis.

Prognosis.—The prognosis of mitral incompetence is more favourable than that of aortic stenosis or incompetence, or mitral stenosis. If the lesion be slight and the conditions of life favourable, the individual may even live to the normal span of life without experiencing much, if any, inconvenience. When, on the other hand, the lesion is severe, as indicated by marked cardiac enlargement, and more especially when symptoms of cardiac failure are present, the patient may live only for a few years. It should be remembered, however, that even when considerable or marked cardiac failure exists, if rest and other suitable therapeutic measures be adopted, the patient may improve for a considerable time. In attempting a prognosis, we should note, among other things, the pulse-rate, the degree of displacement of the right margin of cardiac impairment, and the existence or otherwise of any indications of venous stasis.

With regard to the prognosis of mitral regurgitation, due to *relative* incompetence, this depends upon the cause.

Treatment.—See p. 944.

Pulmonary Stenosis

Pulmonary stenosis may be due to a lesion of the cusps, or of the conus arteriosus.

Ætiology.—The disease is almost invariably congenital; indeed, it is perhaps the most common congenital cardiac affection. When it occurs as an acquired condition, it may be due to acute simple or septic endocarditis, while in some cases the ætiology is obscure.

Symptoms.—The symptoms of the congenital form of the disease will be discussed under Congenital Heart Disease. In the acquired form, in the opinion of some, the degree of dyspnœa is usually not severe, and there is little tendency to cyanosis, clubbing of the fingers, and systemic venous stasis; but perhaps this depends upon the degree of obstruction, and in any case it does not apply in the later stages.

There are physical signs of hypertrophy of the right ventricle (see pp. 955, 956), usually considerable, and it may be even of marked degree, and later it may be of dilatation. There is a systolic murmur, usually harsh, and it may be loud, with its point of maximum intensity in the second intercostal space just to the left of the sternum, which may be audible over a considerable area and may be conducted upwards and outwards towards the left shoulder and it may be to the back, in which event, in the opinion of some, it is some distance to the left of the spine, about the centre of the scapula. It is not audible over the vessels of the neck. There is generally a systolic thrill, as a rule rough. The pulmonary second sound is usually diminished or practically absent.

Diagnosis.—A systolic murmur in the second or third intercostal space,

or both, just to the left of the sternum is perhaps the most common of all murmurs and certainly so in the recumbent posture, and in a considerable majority of cases is of no significance.

Such murmurs may be found in anæmia (most frequently in this area), may be cardio-respiratory or cardio-pulmonary in origin (often and perhaps generally here), or may be due to excitation of the cardiac action, pathological dilatation of the pulmonary artery (see below), pulmonary stenosis, aortic stenosis, a circumscribed aneurysm of the aorta, and the propagation of a murmur from the third and fourth left intercostal spaces just to the left of the sternum in patency of the interventricular septum or from the apex in mitral incompetence, while in some cases the cause is not understood.

In the differential diagnosis, the following should be considered: The condition of the patient at birth. A history of acute endocarditis subsequently. The question of cyanosis. Whether there is enlargement of the heart, and if so right- or left-sided. Is the murmur only heard or louder on lying down; does it vary with the phases of respiration (see p. 939); is it harsh and loud; and is it audible over the vessels of the neck. Whether there is a thrill, and if present is it rough. Is the pulmonary second sound diminished or practically absent. Does an electro-cardiogram indicate right- or left-sided preponderance.

In pathological dilatation of the pulmonary artery there is evidence of the causal condition, the pulmonary second sound is accentuated, and occasionally a diastolic murmur is present. In aortic stenosis the character of the murmur and of the thrill and, in the absence of dilatation of the vessel, of the second sound resemble those in pulmonary stenosis. But the latter lesion is almost invariably congenital; cyanosis is one of the two chief symptoms; the character of the pulse differs; there is evidence of hypertrophy of the right and not left ventricle; the murmur is not audible over the vessels of the neck; and the electro-cardiogram is dissimilar.

Prognosis and Treatment.—See Congenital Heart Disease.

Pulmonary Incompetence

Pulmonary incompetence is the rarest of all valvular diseases.

Ætiology.—The morbid affection may be the result of antecedent acute endocarditis. It is, however, generally due to dilatation of the pulmonary artery, *i.e. relative* incompetence. This may occur in conditions which cause increased pressure in the pulmonary circulation, such as chronic mitral disease, especially stenosis, pulmonary fibrosis, and emphysema. The lesion is rarely of congenital origin.

Symptoms.—These depend upon the causal and any associated conditions, and are difficult to assess. They are principally those of right-sided failure (see p. 857). Hæmoptysis and epistaxis are occasionally met with.

There is evidence of hypertrophy of the right ventricle (see pp. 955, 956). There is a diastolic murmur, presenting the same character as that of aortic incompetence, with its point of maximum intensity in the pulmonary area, sometimes audible over a considerable area, with a direction of propagation downwards towards the lower end of the sternum, and occasionally a

thrill. When relative incompetence is due to mitral stenosis the murmur is known as the Graham Steele murmur.

In *relative* incompetence, the pulmonary second sound is usually accentuated and this may sometimes be recognised, and there is evidence of the causal condition.

The physical signs of tricuspid incompetence may supervene.

Diagnosis.—The diagnosis of pulmonary incompetence is frequently a matter of considerable difficulty. The lesion with which it is most likely to be confounded is aortic incompetence, because the point of maximum intensity of the murmur of the latter is often along the left border of the sternum from the level of the second to the fourth intercostal spaces. The differential diagnosis between these two conditions has been discussed on pp. 934, 935. The physical signs of pulmonary incompetence and patent ductus arteriosus resemble each other; in the case of the latter the murmur occupies both systole and diastole.

In *relative* incompetence there is evidence of the causal condition.

Prognosis.—When due to organic disease and when unaccompanied by any other valvular lesion, the prognosis in pulmonary incompetence may not be unfavourable; instances, indeed, have been recorded in which life has been prolonged almost to the normal span. In *relative* incompetence, on the other hand, the prognosis is usually very serious. Death in either case may result from right-sided cardiac failure, bronchitis or broncho-pneumonia, or pulmonary tuberculosis.

Tricuspid Stenosis

Ætiology.—This is similar to that of mitral stenosis. The affection commences much more commonly in early life, and is much more frequent in females than in males. In the great majority of cases it is the result of an antecedent attack of acute endocarditis of rheumatic origin. There is usually also mitral stenosis, and not infrequently, in addition, aortic valvular disease. The lesion is rarely of congenital origin.

Symptoms.—Cyanosis and shortness of breath on exertion are the chief symptoms. There may be coldness of the extremities. Systemic chronic venous congestion is prone to occur.

The apex-beat may be displaced to the left, and there is evidence of enlargement of the right auricle (see p. 956). There is a diastolic murmur, presenting the same features as that of mitral stenosis (see p. 937), with its point of maximum intensity in the tricuspid area, usually limited in extent but occasionally propagated to the right. A thrill, also diastolic in time and presenting the same character as in mitral stenosis, and having its point of maximum intensity in the tricuspid area, is frequently present. The first sound in the tricuspid area may be short and accentuated. There is often distension and pulsation of the jugular veins. When pulsation of the liver is present, it is of the auricular type. There are usually physical signs of some other form of chronic valvular disease (see Ætiology).

Auricular fibrillation may supervene, in which event pulsation of the liver is of the ventricular type.

Diagnosis.—As tricuspid stenosis is usually associated with mitral stenosis, in a considerable proportion of cases the lesion is overlooked.

The differential diagnosis from mitral stenosis is often a matter of great difficulty. The following is in favour of tricuspid stenosis: the early appearance of marked cyanosis and extensive dropsy; evidence of enlargement of the right auricle; a murmur with its point of maximum intensity strictly in the tricuspid area; and Mackenzie was of opinion that when pulsation of the liver is of the auricular type tricuspid stenosis in all probability exists.

It should be remembered that both tricuspid stenosis and mitral stenosis may rarely be present. In this event, two murmurs with separate points of maximum intensity, or a murmur with its point of maximum intensity midway between the tricuspid and mitral areas may be detected.

Prognosis.—The prognosis in this affection is by no means easy. The question largely depends upon whether mitral stenosis also exists, and if so, in what degree. When both lesions are present, the prognosis is usually very unfavourable.

Treatment.—See p. 944.

Tricuspid Incompetence

Ætiology.—It should be noted that the reflux of a certain amount of blood through the tricuspid orifice may occur under physiological conditions. In severe muscular exertion, for example, in which the intracardiac pressure on the right side of the heart is excessive, a natural function of the tricuspid valve is to provide for a certain amount of regurgitation, and thus afford relief to the temporary embarrassment due to distension of the right ventricle.

Pathological tricuspid incompetence is rarely congenital, and when it is, the condition is usually associated with pulmonary stenosis. Apart from those of congenital origin, there are two classes of cases: (1) Those in which the incompetence of the valve is primary; that is, due to a lesion of the cusps themselves—a rare condition; and (2) cases of *relative* incompetence, in which the cusps are normal. The latter constitute the great majority of cases.

With regard to the first group, the lesion may be the result of a previous attack of acute endocarditis, in which case there is generally tricuspid stenosis, and it may also be mitral or aortic valvular disease.

Relative incompetence is always consequent on conditions which cause increased pressure in the pulmonary circulation—such as chronic mitral disease, especially stenosis, pulmonary fibrosis and emphysema—pulmonary stenosis and incompetence, acute febrile affections, acute myocarditis, chronic myocardial disease, and anæmia.

Symptoms.—These depend upon the causal and any associated conditions, and the degree of the regurgitation. If the first two are favourable and the third is slight, the condition may be latent. Otherwise, shortness of breath on exertion and cyanosis are the principal symptoms, and other indications of right-sided failure are apt to supervene.

In organic tricuspid incompetence, there may be physical signs of enlargement of the right ventricle, and it may be of the right auricle (see pp. 955, 956). There is usually a systolic murmur, presenting the same character as that of mitral incompetence, with its point of maximum intensity in the tricuspid area. Its area is generally small, but sometimes the murmur

is conducted to the right and now and then is audible at the angle of the right scapula. Occasionally there is a systolic thrill, usually not rough. In the absence of a mitral or pulmonary lesion, the pulmonary second sound is diminished. There may be visible distension and it may be also pulsation of the jugular veins. If the vein is emptied from below by means of the finger and its upper extremity kept closed by pressure, it rapidly fills from below. The pulsation is usually of the ventricular, but occasionally of the auricular, type. The liver may be enlarged and may also be pulsating, the pulsation being systolic in time—unless tricuspid stenosis co-exists. There are generally physical signs of some other variety of chronic valvular disease (see Ætiology).

In *relative* incompetence, the physical signs of the causal and any associated conditions are present. A murmur is less frequent.

Diagnosis.—Tricuspid incompetence is very frequently overlooked because in the vast majority of cases there are signs of a causal or associated affection. On the other hand, it should be noted that, as in the case of mitral incompetence (see p. 939), a systolic adventitious sound in the tricuspid area may be due to other causes than incompetence. A correct diagnosis may be made by a consideration of the clinical features described above.

The differential diagnosis from mitral incompetence should be thought of.

Prognosis.—The prognosis of tricuspid incompetence depends upon the cause and associated condition. When the affection is due to organic disease, the outlook is serious.

With regard to *relative* tricuspid incompetence, when this is the result of left-sided valvular disease it is usually serious; it may be the precursor of a fatal termination in the near future. When, on the other hand, it is due to chronic pulmonary affections, acute febrile affections or anæmia, the prognosis may be good.

Treatment.—See below.

Treatment in Chronic Valvular Disease

The ætiology should be reviewed. In this connection, the treatment of syphilitic aortitis is described on pp. 979-981.

Explicit and detailed instructions with regard to his manner of life should invariably be given to the patient. The importance of always living within the limits of the heart's strength should be emphasised (see pp. 862, 863). As already mentioned, I am of opinion that in aortic incompetence the more strenuous forms of physical exertion should be avoided.

In children and young adults, preventive should be adopted against recurrent attacks of acute endocarditis; in all cases of chronic valvular disease the question of focal sepsis should receive attention, with the object of diminishing the risk of septic endocarditis; and, particularly in mitral stenosis, special care should be taken to avoid respiratory affections.

The various measures which may be applicable to any form of heart disease, described on pp. 863–875, should be considered in detail.

Surgical treatment in the form of valvulotomy, both by the auricular and ventricular routes, has been performed in a number of cases of mitral stenosis.

This procedure should be regarded as in an experimental stage. The mortality is high. Again, the change from mitral stenosis to incompetence is of doubtful value.

FREDERICK W. PRICE.

DISEASES OF THE MYOCARDIUM

Affections of the myocardium are of profound importance. It has been pointed out that valvular defects, diseased conditions of the blood vessels and disturbances of the cardiac mechanism should also be regarded from the point of view of their relation to the myocardium, and not so much as specific affections in themselves. It has also been noticed that, along with valvular lesions, coincident changes in the cardiac musculature, the aorta, or coronary arteries are, as a rule, present. We are, however, now concerned with affections of the myocardium occurring independently of valvular disease.

MYOCARDITIS

The varieties which may be met with are: (1) Acute (*a*) simple and (*b*) suppurative; (2) chronic; and (3) tuberculous myocarditis.

Suppurative myocarditis is of uncommon occurrence. It may be due to direct extension in infective endocarditis or to pyæmia. In this condition large abscesses in the myocardium are rare; they may perforate into the ventricle or pericardium. Minute abscesses, on the other hand, generally at the base of the left ventricle, are not rare. Chronic myocarditis will be discussed under Chronic Myocardial Disease.

Tuberculous myocarditis is almost always the result of extension from a tuberculous pericarditis. It usually takes the form of miliary tubercles.

ACUTE SIMPLE MYOCARDITIS

Strictly speaking, by this term is meant acute inflammation of the heart-muscle, but it is generally employed to include also morbid changes of a degenerative nature and I shall use the term in this sense.

Ætiology.—Acute simple myocarditis is most common in childhood and adolescence. Acute and subacute rheumatism, in one of its forms (see p. 913), accounts for the majority of cases. It may also be caused by diphtheria, influenza, acute pneumonia, small-pox, typhoid fever, and some other acute infective diseases. Some degree of myocarditis is present in at least most cases of endocarditis and pericarditis.

Pathology.—In some cases, especially in diphtheria, there is granular, hyaline and fatty degeneration followed by necrosis of the muscle-fibres, due to the direct action of the toxin, with cellular infiltration around. In others, particularly in rheumatism, the interstitial connective tissue exhibits cellular infiltration, but there is also degeneration of the muscle-fibres. Some

writers recognise two forms of myocarditis—the parenchymatous and the interstitial; in most cases, however, both the parenchyma and interstitial tissue are affected. In rheumatic myocarditis what are called *Aschoff's nodes*, described on p. 289, are often to be found, and, in the opinion of many, are pathognomonic of the rheumatic infection. Later, they become converted into fibrous tissue.

Dilatation of one or more chambers of the heart supervenes.

Acute simple myocarditis may be followed by—(1) Complete resolution in which no permanent changes supervene; or (2) the formation of fibrous tissue, which tends to contract as life advances, and which may occur in limited areas or may involve the whole myocardium. The latter condition is known as chronic myocarditis or fibrosis of the myocardium (see p. 949).

Symptoms.—In the first place, the reader is referred to the remarks on p. 913.

The clinical picture of acute myocarditis exhibits great variation as regards severity in different cases. On the one hand it may be indefinite and in rare instances the condition may even remain latent throughout its whole course, while on the other it may amount to a very serious or even grave illness.

The onset may be insidious, or there may be a definite change in the clinical picture of the causative disease. If pyrexia be already present, there may be a further rise of temperature, or if there has been no pre-existing pyrexia it may develop; it may be signalised by a rigor. The patient may complain of shortness of breath, palpitation, præcordial discomfort or pain. Not infrequently vomiting occurs, and indeed may be the first symptom. Cardiac failure, usually both-sided, may occasionally be of very severe degree. In some acute infective diseases, particularly diphtheria (see pp. 100, 102), there may also be acute peripheral circulatory failure.

The pulse is generally increased in frequency, but even bradycardia may very occasionally be present. It is feeble and soft. The blood pressure is usually diminished. In some cases there are extrasystoles (Fig. 42), or partial heart-block (Fig. 43), or auricular fibrillation, or complete heart-block, the second being most common and the fourth exceptional. There is usually dilatation of the heart, generally both-sided (see p. 857). In severe cardiac and peripheral circulatory failure the dilatation may be considerable and rapid, even early in the disease. If there is considerable dilatation of the left ventricle, there may be a soft diastolic murmur in the mitral area—the so-called relative or functional mitral stenosis (see p. 938). The second sound in the pulmonary area is sometimes accentuated and occasionally reduplicated.

A moderate leucocytosis and also a slight or moderate secondary anæmia may be present.

In some acute infective diseases, *e.g.* diphtheria and acute pneumonia, especially the first, there may be both cardiac and peripheral circulatory failure.

Diagnosis.—The diagnosis of acute simple myocarditis is often exceedingly difficult. The recognition of a mild form occurring during or after the febrile stage of any acute infective disease may be arrived at from a

consideration of the symptoms already enumerated. The presence of severe myocarditis may be presumed when there are indications of severe cardiac failure and it may also be severe peripheral circulatory failure coming on rapidly during the course of an acute infective disease, and out of proportion to the severity of the latter, an increase of cardiac impairment being perhaps especially significant. The occurrence of auriculo-ventricular block during

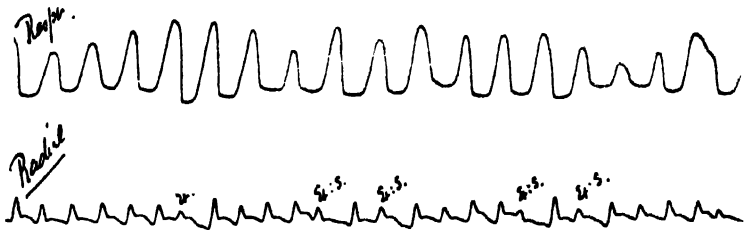

Fig. 42.—Tracing of the radial pulse, from a child suffering from croupous pneumonia, showing extra-systoles. Note the slight pulsus alternans following the extra-systoles

the course of an acute infective disease is indicative of myocardial involvement, and auricular fibrillation and extra-systoles are suspicious.

It may be necessary in any given case to differentiate acute myocarditis from acute endocarditis, and this is often a matter of extreme difficulty, for it should be remembered that both conditions may co-exist, and a mitral systolic murmur may be due to either (see also pp. 922, 923).

Prognosis.—This exhibits great variation. In the milder forms, recovery

Fig. 43.—Simultaneous tracings of the jugular and radial pulses, from a case of acute myocarditis occurring during diphtheria, showing partial heart-block. Every third stimulus from the auricle fails to reach the ventricle.

is the rule if early and adequate measures be adopted. The prognosis of the very severe forms is very grave, the mortality being high; the course of the disease is rapid, a fatal termination occurring usually within a week, and in some cases even within 24 hours, although life may be prolonged for several weeks. Sudden death is particularly prone to occur in diphtherial myocarditis, and may take place even when the patient is considered convalescent. Among the symptoms of bad omen are marked pallor, restlessness, syncopal attacks, vomiting, a greatly accelerated pulse of low tension, bradycardia, and a modifi-

cation of the heart-sounds resembling the fœtal type. As already noted, acute myocarditis may be followed by resolution, or by fibrosis of the myocardium.

Treatment.—This is of great importance.

The treatment of the causative disease should be adopted.

If the condition is at all severe, the measures regarding rest described under acute simple endocarditis (see p. 917) are applicable, excepting that the period of convalescence is not so long. Otherwise the reader is referred to the various therapeutic measures, including for peripheral circulatory failure, described on p. 875.

For acute myocarditis in diphtheria, see also pp. 108, 109.

DISEASES OF THE CORONARY ARTERIES

Before dealing with the various forms of chronic myocardial disease, it may be advisable to make some observations regarding diseases of the coronary arteries, as they bear an important causal relation to some of them, coronary disease being usually accompanied by morbid changes in the cardiac musculature.

Syphilitic mesaortitis and atheroma of the ascending aorta may give rise to narrowing or complete occlusion of the orifice of one or both of the coronary arteries.

Atheroma and, in the opinion of some, rarely syphilitic arteritis may affect the coronary arteries themselves, and result in narrowing or complete occlusion.

If the orifice of one of the coronary arteries be completely and abruptly closed, due to one of the causes mentioned, sudden death occurs. In those cases in which occlusion is only partial, or is gradual, atrophy of the muscle-cells with secondary fibrosis, *i.e.* ischæmic fibrosis of the myocardium or, less frequently, fatty degeneration, or both, usually ensues.

If one of the larger coronary arteries be completely and abruptly closed as the result of one of the causes mentioned, either infarction or sudden death results; while if the occlusion is only partial or gradual, ischæmic fibrosis, or fatty degeneration, or both, generally follow. If one of the smaller coronary arteries be completely and abruptly closed, infarction occurs; while if the occlusion is only partial or gradual, ischæmic fibrosis or fatty degeneration commonly ensues.

Complete occlusion of a coronary artery the result of atheroma is in the great majority of cases sudden and due to thrombosis. It is to be noted, however, that thrombosis does not necessarily give rise to occlusion, for the clot may not completely fill the lumen of the vessel. Complete occlusion in atheroma is sometimes the result of progressive narrowing of the lumen of the vessel caused by the disease-process itself, in which event the occlusion may or may not be completed by thrombosis. Complete and sudden occlusion is also rarely caused by embolism.

From the foregoing it will be seen that coronary occlusion and thrombosis are not synonymous terms, and this should be noted.

The causes of atheroma are described on p. 1038.

In conclusion, it is to be observed that while pain of cardiac origin is especially apt to occur in coronary disease, the latter is frequently present without the former.

CHRONIC MYOCARDIAL DISEASE

Of the various forms of chronic myocardial disease with which we have to deal, the most common are chronic myocarditis, fibrosis of the myocardium, fatty degeneration, and fatty infiltration.

CHRONIC MYOCARDITIS: FIBROSIS OF THE MYOCARDIUM

By chronic myocarditis is meant an increase of the interstitial tissue of the muscular wall, the muscle-fibres being largely replaced by fibrous tissue, which consequently contracts, and those which remain generally exhibit a varying degree of degeneration. The term chronic myocarditis connotes a productive or formative inflammatory process. Fibrosis of the myocardium is, however, frequently the result of other causes, for example, secondary to atrophy of the muscle-cells which may occur in disease of the coronary arteries, *i.e.* ischæmic fibrosis (see p. 948), and in the past chronic myocarditis has often been erroneously used to include such. It is better not to employ this term, and to use only that of fibrosis of the myocardium.

Ætiology.—Fibrosis of the myocardium is more common in late middle or elderly life, and in males. The condition may be a sequel to acute myocarditis. It may be due to an extension from the valves in chronic endocarditis, which is of common occurrence. Local fibrosis may be secondary to acute endocarditis or pericarditis. Fibrosis may be caused by syphilis. In such cases it may be the result of a diffuse primary chronic inflammation; or of coronary disease (see p. 1032); or, rarely, of gummata. There is a considerable diversity of opinion as to the frequency of the first. Some (amongst whom was the late A. G. Warthin) believe it is very common. The general consensus of opinion, however, with which I fully agree, is that it is of infrequent occurrence, and that the fibrosis is usually of ischæmic origin. Atheroma of the coronary arteries is perhaps the most common cause of fibrosis, in which case there may be co-existing fatty degeneration. The condition is occasionally due to chronic venous congestion of the myocardium, the result of chronic valvular disease or of chronic pulmonary disease, or to an old infarct. Not rarely it is impossible to determine the cause. In this connection, I am of opinion that it is at least possible that the same causes which produce atheroma, mentioned on page 1038, may give rise to fibrosis of the myocardium, independent of coronary disease.

Pathology.—The morbid affection may be general or local in its distribution, the latter being usually due to coronary disease. When the affection follows acute myocarditis, a more or less diffuse fibrosis, usually most marked beneath the pericardium and endocardium, is found. In both forms the auricles are little, if at all, affected, and the left side of the heart is much more commonly affected than the right, especially in the neighbourhood of the apex and the lower part of the interventricular septum. When the condition is the result of chronic venous congestion, however, it is more in evidence on the right side of the heart. There is an increase in the thickness of the cardiac wall—the so-called false hypertrophy—and ultimately dilatation occurs. White masses of fibrous tissue, varying in size from that

of a pea to a five-shilling piece or even larger, and irregular in shape, are to be observed replacing portions of the cardiac wall or interventricular septum. When the condition has continued for some time and the increase of fibrous tissue is extreme, the affected muscle-fibres may be entirely replaced by dense scar-like tissue.

See also pathology of causative condition.

Symptoms.—The reader is referred to the chapter on Cardiac Failure.

The clinical picture varies considerably in different cases. In rare instances, the disease is latent until a fatal termination occurs. In most of these cases, however, there had been symptoms on physical exertion for which the patient neglected to seek medical advice, or had not noticed; and also there would have been abnormal findings on clinical or instrumental examination.

The most common symptoms are shortness of breath and fatigue; less frequently discomfort or pain and palpitation; and occasionally there is slight cyanosis of the face; in each case referred to exertion. When the morbid affection is due to coronary disease, pain is apt to be the dominant subjective symptom. As a rule, sooner or later, these symptoms become more easily induced, and others supervene, in each case generally gradually. Usually the failure is both right- and left-sided (see p. 857) with, it may be, one predominating. While the congestive type of failure is very much more common, symptoms of cerebral anæmia and angina pectoris are not infrequent, and Adams-Stokes syndrome is occasionally met with. Ultimately there may be indications of severe, or even extreme, failure.

The pulse may be increased in frequency, or occasionally there may even be bradycardia. Its character varies considerably: it is usually fuller than normal, with increased pressure, although the latter is not pronounced unless there is co-existing hypertension or chronic renal disease. The apex-beat is usually displaced downwards and to the left, its area and force are sometimes increased, the area, however, being proportionately greater and the force relatively less than in pure hypertrophy. The area of cardiac impairment is generally increased in all directions. The first sound at the apex is often prolonged and muffled, while at the base it is occasionally diminished and may be scarcely audible or even absent. There is often, if not usually, heart-block, generally one of the three degrees of the auriculo-ventricular variety, but it may be bundle-branch or arborization block; or auricular fibrillation may supervene. A mitral, and less frequently a tricuspid, systolic murmur may be present.

If there is hypertension, see pp. 1066 1068. Not infrequently there are indications of general atheroma.

Diagnosis.—It is probable that chronic myocardial disease is overlooked more frequently than any other cardiac morbid affection. The two chief reasons for this, in my opinion, are a failure to obtain an accurate history regarding subjective symptoms on physical exertion and to detect enlargement of the heart, the latter especially in cases in which the apex-beat is either faint or absent. As regards the first, careful inquiry should be made as to whether the patient experiences any cardiac symptoms on physical exertion which formerly he was able to do (see p. 852). Respecting the second, while I do not share the view that percussion, provided this is performed with competence, is of little or no value, naturally examination

by the X-rays is of first importance. A combination of the existence of subjective symptoms on physical exertion and, it may be, of objective signs of cardiac failure together with enlargement of the heart and, it may be, modification of the character of the pulse, of the cardiac sounds and rhythm, and of the blood pressure, in the absence of other causes, is of especial value. An X-ray examination may also reveal co-existing atheroma of the aorta. An examination by the electro-cardiograph may be of supreme value. If there is auriculo-ventricular block, bundle-branch block, or intraventricular block, if persistent, the presence of chronic myocardial disease may be assumed. An electro-cardiogram may also reveal associated coronary disease. The differential diagnosis between fibrosis of the myocardium and fatty degeneration is described on p. 952.

It is necessary to distinguish chronic myocardial disease in which relative mitral incompetence has supervened from organic mitral incompetence, which may be very difficult. In the former, there is no history of chronic valvular disease, the subjective symptoms are frequently out of proportion to the physical signs, and angina pectoris and syncopal attacks are of more frequent occurrence.

Prognosis.—This varies very considerably. Taken as a whole the outlook is serious, but this may be partly due to the fact that as a rule the malady is not recognised in its early stages. The affection tends to be progressive. The various points dealt with in the section on Prognosis should be considered. Those of special importance are the ætiology and any associated morbid condition, the size of the heart, whether the lesion is progressing, the cardiac rhythm, and the question of heart failure and that of angina pectoris.

The most frequent cause of death is congestive heart failure. Sudden death is not rare, and may be due to angina pectoris, rupture of the heart, or other causes.

Treatment.—The ætiology should be reviewed with the object of treating the underlying cause, and the same applies to any co-existing associated morbid condition.

The various therapeutic measures described on pp. 861–875 should be considered carefully and in detail.

FATTY DEGENERATION

In fatty degeneration the muscle-fibres are more or less replaced by fat.

Ætiology.—Heredity is a factor. The condition is more common in males and in later middle or elderly life. Among the causes are: severe altered states of the blood, such as pernicious anæmia and leukæmia; chemical metallic poisoning, *e.g.* by phosphorus, arsenic, antimony, alcohol and chloroform; coronary disease, in which case, however, there is usually associated fibrosis and in much more degree, chronic pulmonary disease and in long-standing chronic valvular disease, giving rise to obstruction of the pulmonary circulation; as a sequel to marked fatty infiltration; and occasionally in diabetes.

Pathology.—The affection may be general or local in its distribution the latter being the more common. In both cases, but especially in the local

form, the ventricles are affected to a greater degree than the auricles, and the left ventricle than the right, except in chronic venous congestion of the lungs, and the musculi papillares and the muscle beneath the endocardium are principally involved. The heart may or may not be enlarged; indeed, in pure degeneration it may be even smaller than normal. In this connection it may be stated that fatty degeneration may accompany or succeed dilatation or hypertrophy, while, on the other hand, dilatation may follow degeneration. The organ is softer in consistence and flabby, and is more easily torn. The colour may be uniformly pale yellowish, or buff, or light yellowish brown—the so-called "faded-leaf" colour. The condition may, however, occur in patches, resulting in a streaked or mottled appearance as a whole, which has been likened to that of the breast of a thrush—'thrush's breast,' or to that of the fur of a tabby cat—"tabby cat striation." On microscopic examination of a section which has been stained with osmic acid, the small fat globules are seen inside the muscle-fibres, their envelopes being blackened by the acid.

Symptoms and Diagnosis.—The clinical picture of fatty degeneration resembles that of fibrosis of the myocardium, and in the opinion of some, a differential diagnosis is not possible, but I do not share this view. The following points are of help: In fatty degeneration symptoms associated with cerebral anæmia, general lassitude, debility, impairment of digestive functions, and a subnormal temperature are of more common occurrence; pain excepting angina, the congestive type of failure, and the Adams-Stokes syndrome are less frequent; the countenance may be pale and waxy; and, as in the case of fatty infiltration, there is a tendency to cyanosis on exertion—the association of cyanosis with dyspnœa on exertion being one of the most distinctive features of both. Usually the size and force of the pulse are less; the blood pressure is lower; the force of the apex-beat and any enlargement of the heart are less; the first sound is of shorter duration and may be sharp and clear; the second sound in the aortic area is less loud; and general atheroma is not so frequent.

Prognosis.—This somewhat resembles that of fibrosis of the myocardium. Here also the duration of life varies very considerably but, taken as a whole, the outlook is serious. In the acute forms, *e.g.* when due to altered states of the blood, the immediate prognosis is grave but the ultimate outlook not infrequently favourable. In the chronic forms, on the other hand, the opposite is the case. With further knowledge, it is now clear that the risk of sudden death has been much exaggerated.

Treatment.—The treatment of fatty degeneration is the same as that of fibrosis of the myocardium.

FATTY INFILTRATION

Synonyms.—Fatty Heart; Cor Adiposum.

Fatty infiltration consists in an excess of fat in those situations in which it is naturally found, and also in its deposit between the fasciculi of the cardiac musculature.

Ætiology.—Heredity is certainly a factor, and the condition is more common in males, and during or after middle life, being rare in early life

and comparatively so before middle age. It is usually associated with general obesity, though not always in proportionate degree, a generous appetite, and lack of exercise and fresh air. It is more especially found in over-indulgence in carbohydrates, fats and alcohol, particularly malt liquors and sweet wines, and faulty metabolism is generally present. The malady is also apt to occur in those suffering from affections of the lungs which cause embarrassment of the pulmonary circulation, such as emphysema, cirrhosis and chronic fibroid tuberculosis.

Pathology.—The affection is generally most marked over the right ventricle. The deposit of fat commences in the subepicardial fat, and may even extend to the subendocardial tissue. It is chiefly distributed along the arterial branches, often causing atrophy of the muscle-fibres by compression, and in some instances the latter become the seat of true fatty degeneration due to interference with their nutrition. In fatty infiltration, more or less dilatation of the cardiac chambers is usually present, and is often accompanied by hypertrophy.

Symptoms.—The patient is usually stout and flabby. The subjective symptoms are those of an enfeebled circulation. Exertion is frequently accompanied by fatigue, a tendency to perspire, dyspnœa with, it may be, slight cyanosis, and occasionally a sense of oppression in the chest, and giddiness or faintness. There may be early fatigue, and giddiness or faintness or mental effort, impairment of memory and the patient may be soporose, although, on the other hand, he may complain of insomnia.

The character of the pulse varies: usually it is weak, there is hypotension and the vessel wall is not thickened; but on the other hand it may present the opposite features. The cardiac impulse is generally feeble unless hypertrophy is also present. The area of cardiac impairment is usually increased. The heart sounds, especially the first, may be weak, low in tone, and muffled; while occasionally a mitral, and less frequently a tricuspid, systolic is present.

Later, there may be indications of a more pronounced degree of cardiac insufficiency.

Diagnosis.—Fatty infiltration may be diagnosed from the features described, occurring in a person who is the victim of obesity.

Prognosis.—If appropriate therapeutic measures be carried out, the prognosis is usually favourable; otherwise the condition is apt to be progressive. If the condition persist for some time, true degeneration is apt to arise. Again, in very severe fatty infiltration, rupture of the heart wall has been known to occur.

Treatment.—If, as is usually the case, general obesity is present, it should be treated (see pp. 481, 482). Regulated exercise in the open air is valuable, and systematic and graduated exercises and massage (see pp. 864, 865) may be tried. Spa treatment is not infrequently helpful.

HYPERTROPHY AND DILATATION OF THE HEART

Enlargement of the heart may be due to hypertrophy; or to dilatation; or, as is usually the case, to both together—excentric hypertrophy.

In simple hypertrophy there is an increase in the thickness of the walls of one or more of the cavities of the heart. The hypertrophy may include

the musculi papillares, columnæ carneæ, and the musculi pectinati. In dilatation there is an increase in the capacity of one or more of the chambers of the heart.

Ætiology.—Simple hypertrophy is a physiological reaction to continued overwork. Among the causes are aortic stenosis, essential hypertension, chronic interstitial nephritis, secondary contracted kidney, and diffuse hyperplastic sclerosis. It may also be due to long continued severe physical effort, as in heavy manual labour, athletic training and military training, chronic adhesive pericarditis, especially if there are extra-pericardial adhesions, and possibly continued excitation of the cardiac action, as in chronic thyrotoxicosis. In the case of the first, the hypertrophy is left-sided; in the second and fourth, it is at least chiefly left-sided; and in the third, it is likely to be general.

The causes of hypertrophy of the right ventricle are conditions which give rise to increased pressure in the pulmonary circulation, such as chronic mitral disease, especially stenosis, pulmonary fibrosis and emphysema, and pulmonary stenosis and incompetence.

For the development of full hypertrophy, an adequate blood supply is necessary, and in this connection the integrity of the coronary arteries is of fundamental importance.

Looking at the subject from the clinical standpoint, there are two kinds of cardiac dilatation, namely physiological and pathological. The former may be met with as a transient condition in severe muscular exertion. It also occurs in the form of compensatory dilatation in some varieties of chronic valvular disease (see pp. 927–930): of the left ventricle in aortic incompetence and in mitral incompetence; of the left auricle in mitral stenosis; of the right ventricle in pulmonary incompetence and in tricuspid incompetence; and of the right auricle in tricuspid stenosis. In this group there is also hypertrophy of the respective chambers.

Pathological dilatation is associated with impairment of the function of tonus or tonicity and cardiac failure. The affected chamber does not empty itself, and as the dilatation progresses, the contraction of the chamber becomes less effective and the amount of blood proportionately increases.

The condition may occur in any of the following: secondary to simple cardiac hypertrophy, however caused (see above); secondary to compensatory dilatation (see above); chronic myocardial disease; coronary occlusion; acute infective diseases; toxæmias; severe or prolonged pyrexia from any cause; the various forms of anæmia; and primary cardiac strain. In the first two there is hypertrophy and dilatation together.

In acute and subacute rheumatism, diphtheria, and in influenza, dilatation may be acute. It should also be noted that a common clinical condition in which acute dilatation occurs is the supervention of a new rhythm, such as auricular fibrillation.

Dilatation of the auricles is especially apt to occur in auricular fibrillation.

The causes of dilatation of the right side of the heart are the same as those of pathological *relative* tricuspid incompetence (see p. 943). In addition, in cardiac failure, whatever the cause, the pressure in the right heart rises and the chambers dilate.

Some of the causes of hypertrophy, by acting quickly, before there is time for hypertrophy, may produce dilatation; this is especially the case where the muscular fibres are already impaired.

Pathology.—Hypertrophy of the heart may be general or local, the latter being more common. In the former all the chambers are affected, the ventricles being more affected than the auricles. When the condition is local more than one chamber is usually involved, in varying degree.

When the left ventricle is affected, the apex of the heart is accentuated, and the whole organ is elongated and rather conical in form. When the right ventricle is concerned, the apex is less pronounced, and the whole organ broader and somewhat quadrate in form. The eccentric form of hypertrophy may give rise to enormous enlargement, in which case the organ is often spoken of as a "beefy heart" or a "cor bovinum." This is particularly apt to occur in aortic valvular disease.

Cardiac dilatation rarely affects one chamber alone, all of them being usually involved in some degree, although unequally so. When the condition is more or less general the organ approaches the globular form, especially when the right side is affected.

With the increase in the capacity of the ventricles, the dimensions of the auriculo-ventricular orifices also increase, with consequent *relative* incompetence. In dilatation of the auricles there is usually enlargement of the venous channels.

Symptoms.—In hypertrophy and compensatory dilatation there may be subjective symptoms associated with the causal affection. In pathological dilatation, there are symptoms of cardiac failure, in varying degree (see pp. 852–856). These may come on rapidly in the acute forms, and more gradually in the more chronic cases. In many of the cases associated with the supervention of a new cardiac rhythm the dilatation may sometimes take place so rapidly that in the space of a few hours there may be severe failure. In cardiac hypertrophy or cardiac dilatation the following may be present:

In hypertrophy of the left ventricle, the pulse-rate is apt to be rather slower. There may be some bulging and widening of the intercostal spaces to the left of the sternum, especially where the hypertrophy occurs during the growing period of life. The apex-beat may be displaced downwards and outwards, its area and force increased, and its out-thrust slower and longer than normal. The increase in force together with slowing of the out-thrust—the so-called "heaving" apex-beat—is the most characteristic feature of the condition. The area of cardiac impairment may be increased both from above, downwards and transversely. The first sound may be long, low in pitch and muffled, and the aortic second sound may be accentuated.

In hypertrophy of the right ventricle there may be, more especially in children, a certain amount of bulging in the region of the ensiform cartilage, while not infrequently there is pulsation in the epigastrium, which is inverted. When the condition is marked, there may be a heaving impulse in the epigastrium, and over the lower sternum and costal cartilages, and in such cases even in a more marked degree than in the case of the left ventricle. The apex-beat is displaced chiefly to the left and only slightly downwards, and may be normal, diffuse and indefinite, or altogether invisible. When the right ventricle is much enlarged, that chamber may displace the left ventricle backwards, so that the clinical apex-beat is formed entirely by the right, instead of the left, ventricle; in these cases systolic recession over the lower part of the præcordium is sometimes observed. Systolic recession in the third, fourth

and fifth intercostal spaces between the margin of the sternum and the parasternal line on the left side, or in the fourth and fifth intercostal spaces on the right side, may be present. The area of cardiac impairment is usually increased, especially to the right. The left border may also be displaced outwards, but rarely extends beyond the nipple line. The first sound in the tricuspid area is not infrequently louder than normal, and the second sound in the pulmonary area is usually accentuated.

In enlargement of the left auricle, the area of impairment may be higher than normal; when the right auricle is affected, there may be an extension outwards of the area of impairment in the third and fourth right intercostal spaces.

For the results of X-ray examination, see pp. 928–930; and of electrocardiographic examination, pp. 1005–1007.

In cardiac dilatation, the pulse may be more frequent, of smaller amplitude, and weaker, and the blood pressure lower than normal. The apex-beat is displaced chiefly outwards. It may be diffuse and weaker or occasionally tapping in character. The area of cardiac impairment is increased transversely, being more so to the left when the left ventricle is chiefly involved, and vice versa. The first sound may be diminished, and may also be short, sharp and clear, and the long pause may be diminished. A mitral systolic bruit may be present on account of relative incompetency of this valve.

The signs of dilatation of the right ventricle are the same as those of hypertrophy, excepting that there is an absence of a heaving impulse; and a tricuspid systolic bruit may be present, due to relative incompetency of this valve.

The signs of dilatation enumerated above may be modified by those of the cause of the condition or of accompanying hypertrophy.

In the case of chronic valvular disease, any pre-existing murmur or murmurs may become weaker or even inaudible when dilatation occurs.

When cardiac hypertrophy and dilatation co-exist in the same individual, there is a blending of the signs of both.

Diagnosis.—A diagnosis of cardiac hypertrophy or dilatation may be made from the signs described. The most reliable method of determining enlargement of the heart, including of the various chambers, is X-ray examination.

A diagnosis of enlargement of any chamber should not be made merely from displacement of the apex-beat, or the presence of pulsation or impairment of percussion in an abnormal area, for these may be due to other causes, as, for example, morbid conditions of the lungs or pleuræ. Again, a mere increase in the force of the apex-beat is sometimes met with in nervous subjects. The most reliable physical sign of hypertrophy of either ventricle is an increase of force together with slowing of the out-thrust. The diagnosis of enlargement of the left auricle is very difficult; that of the right auricle is more easily detected.

The diagnosis of dilatation from hypertrophy is readily made by comparing the physical signs of both. It is sometimes difficult to recognise great cardiac dilatation, especially of the right ventricle, from pericardial effusion. The matter is dealt with on p. 960. Cardiac dilatation should also be distinguished from those cases of mitral stenosis in which there is an absence of the characteristic murmur at the time of the examination. It is,

further, sometimes necessary to exclude a right-sided pleural effusion displacing the heart to the left.

Prognosis.—That of hypertrophy depends upon the cause. Whatever the cause, however, if long continued it is apt to be followed by pathological dilatation. The outlook of pathological cardiac dilatation depends upon the cause, the size of the heart, the degree of cardiac failure, and its response to treatment.

Treatment.—The treatment of hypertrophy depends upon the causal condition. In pathological dilatation, the first consideration is the recognition and treatment of the cause. In addition, the treatment is that of cardiac failure, and the various therapeutical measures described on pp. 861–875 should be considered in detail.

FREDERICK W. PRICE.

DISEASES OF THE PERICARDIUM

PERICARDITIS

The varieties of pericarditis which may be met with are the acute—which may be divided into the fibrinous or dry, and pericarditis with effusion, which may be sero-fibrinous, purulent, or hæmorrhagic; and chronic adhesive pericarditis or adherent pericardium.

ACUTE PERICARDITIS

Ætiology.—The affection occurs most commonly in young adults, but may be found at any age, according to the infection which causes it, and is more frequent in males. It is generally due to one of the acute infective diseases, especially acute and subacute rheumatism—the most common cause—pneumococcal infections, particularly empyema, and septicæmia and pyæmia, while pulmonary tuberculosis is not rare. It also occurs as a terminal event in various chronic diseases, *e.g.* chronic nephritis, in coronary occlusion with infarction, neoplasm, usually metastatic, and in perforating wounds of the chest.

Sero-fibrinous pericarditis usually begins as the fibrinous form, this being quickly followed by a serous exudate, but it may start insidiously, *e.g.* in tuberculosis.

Purulent pericarditis may result from a general systemic pyæmia occurring in staphylococcal, streptococcal, pneumococcal, and rarely gonococcal infection. It may also follow the direct spread of infection from an adjoining focus of suppuration, as in empyema, or, much less common, a pulmonary vomica. *Hæmorrhagic* pericarditis usually results from tuberculosis or neoplasm.

Pathology.—Acute fibrinous pericarditis may be local or general in distribution. If local, the base of the heart adjacent to the great vessels is principally affected. In the early stages the smooth and shiny pericardium loses its lustre because the exudation of lymph coagulates on the surface,

and this may wholly cover both the visceral and parietal pericardium. This layer of fibrinous exudate may assume great thickness, and the resulting ragged honeycombed appearance has earned for it the title of "bread-and-butter" pericarditis. In at least most cases there is some degree of myocarditis.

Resolution of the fibrinous exudate is usually not complete and organization takes place, the results of which vary from what are called "milk spots" to various degrees of permanent fibrous adhesions between the two layers of the pericardium and adhesions outside the pericardium (see page 961).

A few words about "milk spots" or "soldier's spots" may here be made. These are probably much more often due to pressure outside the pericardium causing friction between the two layers than the result of acute fibrinous pericarditis. They are localized patches on the epicardium which are slightly thickened, smooth, opaque, and of milky-white colour.

In sero-fibrinous pericarditis the serous exudate may vary up to a great amount which may even distend the pericardial sac and produce the pressure on the heart, the adjacent structures in the mediastinum, the lungs, the superior and inferior vena cavæ, and the hepatic veins.

Symptoms.—In *acute fibrinous pericarditis* the clinical picture varies considerably. Occasionally there is an absence of symptoms throughout the whole course. Usually there is a rise of temperature, and occasionally the onset of this complication is signalled by a rigor. There is generally shortness of breath. Discomfort or pain is perhaps usual. It may be in the præcordium or referred to the upper part of the front chest, the neck, the left shoulder, the left scapular region, or upper part of the abdomen. It may be constant and dull, or intermittent and sharp in character. If there is pleuro-pericarditis, particularly if the diaphragmatic pleura is involved, it may be severe and increased by deep breathing and cough. There may be leucocytosis.

The cardiac rate is generally increased. The characteristic physical sign is a friction sound, and occasionally there is a corresponding fremitus. The former usually accompanies ventricular systole and diastole, is of a to-and-fro character, with generally a short pause between the two portions. Sometimes it is only ventriculo-systolic, while at others, when the inflammation involves the auricle, it occurs during auricular systole, ventricular systole, and ventricular diastole, giving rise to triple sounds. In any case, the different portions of the friction sounds do not absolutely coincide either in rhythm or duration with any period of the cardiac cycle, being rather later than any of them and usually heard during portions of more than one period. The adventitious sound is usually first audible over the apex or the base of the heart or over the right ventricle, but later may become audible over the whole præcordium. The area of the maximum intensity is variable, and does not absolutely correspond with any of the valvular areas. As a rule, the sound is either not at all or only slightly conducted, and there is no definite selective direction of propagation. It is of a rubbing quality, and either coarse or grating or fine and creaking, and is superficial, giving the impression of being produced immediately beneath the stethoscope, while moderate additional pressure with the bell of the stethoscope usually causes an increase in its intensity. The locality, the distribution, the character, and the loudness of the friction may quickly change from time to time. It

may also not be so well heard when the patient is lying down as when he is sitting up. The heart sounds are generally audible.

There may be physical signs of dilatation of the heart (see page 756).

In *sero-fibrinous pericarditis* the clinical picture varies with the amount of fluid and the rate at which it accumulates. If the amount is small there may be no symptoms. If, on the other hand, it is considerable or large and especially if the accumulation is rapid, discomfort and pain are usually increased though they may be even less. There may be a sense of oppression in the chest. Generally the patient has an anxious expression, and is pale and it may be cyanosed. Restlessness and insomnia are frequent, and there may be mild delirium, or drowsiness or coma, while occasionally acute cerebral attacks are met with. There may be effects due to pressure on the heart, the great vessels, the trachea, bronchi, lungs, the phrenic nerve, and the œsophagus. There may be such symptoms as faintness, orthopnœa, paroxysmal dyspnœa, an irritating cough, distension of the jugular veins, those of right-sided heart failure, hiccough, and dysphagia.

Unless the amount of fluid is such as to separate completely the two layers of the pericardium, friction sound usually persists.

The cardiac rate is usually increased. If the amount of fluid is large, the systolic blood pressure falls and the pulse pressure is diminished, and the radial pulse may become very small or disappear during inspiration —the pulsus paradoxus. Not infrequently, particularly in children, there is prominence of the præcordium, and the intercostal spaces may be widened or even bulge, as well as the ribs, and there may also be prominence of the epigastrium, which may be due to downward displacement of the left lobe of the liver. Occasionally there is local œdema of the chest wall. There may be diminished expansion of the left chest, and also lessened movement of the diaphragm, especially on the left side. As the amount of fluid increases, the apex-beat becomes less and less definitely felt, until it may be imperceptible unless the heart is fixed to the chest wall by adhesions resulting from a previous pericarditis. The area of cardiac impairment increases in all directions and progressively, in some cases considerably and even very greatly. The shape of the area is affected by a change of position of the patient. In the recumbent position, the base of the cardiac dullness is broadened and the outline of the area of impairment as a whole is globular; and there may be impairment of resonance in the cardio-hepatic angle—Rotch's sign. In the upright position the base becomes narrower and the outline of the area resembles a pear hanging down from its stalk. The foregoing may also be determined by radioscopy. This method of examination may, in addition, show diminution or absence of cardiac pulsation. With an increasing amount of fluid, the cardiac sounds become progressively diminished and muffled. The pressure of the effusion on the left lung may result in dullness of percussion note, tubular breathing, and ægophony over the base—Bamberger's or Ewart's sign. In some cases the electro-cardiograms are similar to those of coronary occlusion.

In *purulent pericarditis* marked tachycardia, persistent and severe pyrexia, which may be of the septic type, often with rigors and sweating, increasing pallor and prostration, and increased leucocytosis may be present.

Diagnosis.—The diagnosis of the fibrinous variety is usually not difficult. It rests upon the detection of the characteristic friction sound.

It should be differentiated from a double endocardial murmur or, if the friction sound be single, from a single one by the absence of the features already described. Moreover, the position, intensity, and character of the friction may alter in a few hours. It should also be distinguished from pleuro-pericardial friction. In the case of the latter, the friction sound is affected by the different phases of respiration and is abolished by the cessation of breathing. Further, pleuritic friction generally disappears with the effusion of fluid, whereas in sero-fibrinous pericarditis, friction is usually not abolished unless the quantity of fluid is great.

Sero-fibrinous pericarditis can be diagnosed from the clinical picture described, and valuable help may be obtained by X-ray examination. Acute dilatation of the heart, hydropericardium, left localized pleural effusion, pulmonary consolidation, thoracic aneurysm, enlarged glands, abscess of the mediastinum, and, particularly in the case of children, an acute abdominal condition should be excluded.

The differential diagnosis from acute cardiac dilatation is sometimes difficult. In its consideration the following are of help: The matter of ætiology. In dilatation the apex-beat is generally diffuse. The first sound may not only be diminished but may also be short, sharp, and clear. Excepting in mitral stenosis, the area of cardiac impairment does not extend so high; it is increased laterally more than upwards; and its shape is not affected in the manner described by a change of position of the patient. On X-ray examination there is also no diminution or absence of the cardiac pulsation. The abdominal organs are not displaced downwards.

Prognosis.—The immediate outlook in the fibrinous variety depends upon the ætiology of any associated morbid affection; in itself it is not of serious significance. That of sero-fibrinous pericarditis also depends upon the severity of the clinical picture, and the nature and the amount of the serous exudate. It is serious if the effusion is purulent or hæmorrhagic.

The ultimate prognosis in both varieties is related to the extent, the character, and the locality of any resultant chronic adhesive pericarditis.

Treatment.—Naturally the cause and any associated morbid condition should receive attention.

The general treatment is the same as that of acute simple endocarditis (see pp. 917, 918).

In sero-fibrinous pericarditis, paracentesis pericardii should only be considered if there is reason to believe that the amount of fluid is such as to cause very serious embarrassment to the cardiac action, and is comparatively rarely necessary in rheumatic cases. The site chosen for this procedure varies, and more than one may be tried if required, as the fluid may be localized due to a previous attack of acute pericarditis. It may be performed just outside the apex-beat and just inside the area of cardiac impairment. Or high up in the angle between the ensiform cartilage and the left costal margin of the sternum, passing the needle upwards, backwards, and slightly inwards. Or in the fourth, or fifth, or, if the amount of fluid be large, the sixth, left intercostal space close to the sternum. Failing these, if the amount of fluid is large, in the left posterior thoracic wall, in the seventh or eighth intercostal space in the mid-scapular line with the left arm in a raised position.

The treatment of purulent pericarditis consists in incision and drainage

of the pericardial sac, unless the general condition of the patient is too grave to allow of it.

Chronic Adhesive Pericarditis or Adherent Pericardium

In this form of pericarditis there are permanent fibrous adhesions between the two layers of the pericardium.

Ætiology.—The condition may follow acute pericarditis, or may be due to a primary chronic inflammation of unknown ætiology.

Pathology.—Chronic adhesive pericarditis varies considerably in its distribution and severity. The morbid affection may be conveniently divided into four groups, namely: (1) Localized, in which event it is usually situated at the base of the heart close to the great vessels, or near the apex, and the adhesions are generally light. (2) The adhesions are extensive or even complete, but light. (3) They are extensive or even complete, and dense and exhibit much thickness, obliterating the sac and even firmly binding together the visceral and parietal layers—*chronic constrictive pericarditis*. Sometimes the adhesions calcify. (4) The morbid process may occasionally extend outside the pericardial sac to involve the mediastinum—*mediastino-pericarditis*; in which condition there may be adhesions between the pericardium and the mediastinal structures, the chest wall, the pleura, or the diaphragm. In the third and fourth groups the large vessels entering and leaving the heart may be constricted by the adhesions, and this may interfere with the influx and egress of blood. The venæ cavæ are most affected. Constriction of the hepatic veins may give rise to chronic venous congestion of the liver, and ultimately some degree of cirrhosis—*Pick's disease or syndrome, or mediastino-pericardiac pseudo-cirrhosis of the liver*.

In the first and second groups, the condition in some cases gives rise to slight or at the most moderate cardiac enlargement. In the third and fourth, the heart is enlarged and, especially in the latter, it may be considerably so.

There is often co-existent chronic valvular disease, and if so it usually gives rise to cardiac enlargement, and there may also be involvement of the myocardium.

Symptoms.—Taking all cases of chronic adhesive pericarditis, in a large proportion of cases there is an absence of symptoms throughout, and the condition may only be discovered at necropsy, or, if there is calcification, during radioscopy of the chest. The degree of symptoms depends upon how much the morbid affection interferes with the cardiac action and so involves extra work on the part of the heart.

In the first two groups described, some cases in the course of time exhibit slight or moderate cardiac insufficiency.

The third and fourth groups always entail extra work on the part of the heart, and shortness of breath and evidence of congestive failure usually supervene in the course of time. The following signs may be present: Pulsus paradoxus. Prominence or, less frequently, flattening of the præcordium. The cardiac pulsation may be increased in area, and may occasionally extend even from the second intercostal space to the apex-beat and from the right parasternal line to beyond the mid-clavicular line, and may be wave-like and undulatory in character. If there are adhesions between the pericardium and the chest wall there may be systolic retraction in the vicinity

of the apex-beat, of the intercostal spaces on either side of the sternum, of the lower end of the sternum and of the adjacent costal cartilages, and in the epigastrium; and if there are adhesions between the pericardium and diaphragm, there may be the same in the region of the eleventh and twelfth ribs posteriorly on the left side—Broadbent's sign. The apex-beat and the left border of the heart may be displaced outwards, and the force of the former may be increased. There may be little or no change in the position of the apex-beat and that of the heart with a change of position of the patient or on deep respiration. When there are adhesions between the heart and the diaphragm or sternum, there is limitation, or absence of movement during respiration. Diastolic collapse of the veins of the neck (Friedreich's sign) is seldom present. A loud and rough first sound in the mitral area may be met with, and may simulate a presystolic murmur.

Radioscopy will reveal some of the foregoing, and in addition there may be: diminished amplitude of the pulsation of the heart; bands of adhesions connecting the parietal pericardium to the mediastinal structures, the chest wall, the pleura, or the diaphragm; and calcification of the adhesions.

In constrictive pericarditis, hepatic enlargement, ascites, and visible distension of the jugular veins are out of proportion to œdema of the lower extremities. There may be swelling of the face. There is persistent increase in the venous pressure. The pulse is small and the blood pressure is diminished. Pleural effusion is sometimes met with. Unless extra-pericardial adhesions are also present, any enlargement of the heart does not exceed that of moderate degree.

Electro-cardiograms usually show low voltage of the *Q*, *R*, *S* deflections, or diminished amplitude or inversion of the *T* deflections, or both.

Diagnosis.—This may be a matter of very considerable difficulty. A positive diagnosis should not be made from the presence of one physical sign alone excepting perhaps in the case of systolic recession of the sternum itself. It is, however, different when at least several are present, especially if there is right-sided cardiac enlargement and failure in the absence of mitral and chronic pulmonary disease, and particularly if there is a history of acute pericarditis, or of acute or subacute rheumatic infection. Pulsus paradoxus occurs also in sero-fibrinous pericarditis and some other conditions. Slight systolic recession in the epigastrium is not infrequent in health. Systolic recession of the apex-beat, of the intercostal spaces on either side of the sternum, and of the epigastrium may also be due to an enlarged right ventricle; and that of the lateral and posterior walls of the left side of the chest has been observed in marked enlargement of the heart. Systolic recession of the sternum itself is perhaps pathognomonic. An absence of alteration of the position of the apex-beat and of the heart with change of position of the patient or on deep respiration may be found in pleural adhesions. Radioscopy is a valuable aid in diagnosis. Evidence of calcification is pathognomonic.

Constrictive pericarditis may be diagnosed from the clinical picture described. Recurring ascites in the absence of œdema elsewhere is exceedingly suggestive. The result of electro-cardiographic examination is generally of help. The condition should be diagnosed from true cirrhosis of the liver, chronic renal disease, and polyserositis. Such is not difficult.

Prognosis.—The outlook in the first two groups is good, the duration

of life not being affected and the patient's capacity little or not at all. The same largely applies in the third group in the absence of constrictive pericarditis. If such is present, the immediate outlook is not unfavourable but in the absence of successful surgical treatment a life of invalidism is almost always inevitable. The prognosis in mediastino-pericarditis will depend upon the extent of the morbid affection and the degree of any existing cardiac failure.

Treatment.—If such is indicated, the various measures described on pp. 861–973 should be consulted. Otherwise the treatment consists in the consideration of surgical measures in certain cases.

There are two procedures, namely, that recommended and practised by Bauer, and the other by Delorme. The first is employed when there are extensive and firm adhesions between the pericardium and the chest wall. It consists in the removal of several ribs and costal cartilages on the left side over the præcordium, and dividing the adhesions. This is a comparatively simple operation with a relatively low mortality, and is often very successful. The other procedure is used in chronic constrictive pericarditis with an absence of external adhesions. It consists of decortication, *i.e.* the removal from the surface of the heart of as much as possible of the adhesive tissue, and also dividing any adhesions which may constrict the blood vessels. This is a much more difficult and dangerous operation, but in some cases the results have been brilliant.

Surgical measures are only indicated in carefully selected cases and if performed by those with special skill and experience.

HYDROPERICARDIUM

A certain amount of fluid is usually found in the pericardium after death. In hydropericardium, or dropsy of the pericardial sac, the amount is in excess.

The condition is always secondary. It is usually due to cardiac or renal disease, in which event there is generally hydrothorax or ascites, or both. Rarely it is the result of obstruction of the veins by aneurysm, enlarged glands, or new-growths, or of cachectic conditions.

The clinical features are those of the primary affection and of serofibrinous pericarditis except that there is an absence of friction on auscultation.

The prognosis is that of the primary condition.

The treatment is that of the causal affection together with the restriction of the daily amount of fluid and the administration of diuretics. If urgent symptoms appear to demand it, parancentesis may be performed; this, however, is rarely necessary.

PYOPERICARDIUM. (Purulent Pericarditis, see pp. 957, 958)

HÆMOPERICARDIUM

By this is meant the presence of blood in the pericardial sac, occurring apart from pericarditis.

The condition may be due to rupture of the aorta, one of the coronary arteries, or the heart, perforation of the œsophagus, punctured wounds, or the result of purpura or scurvy.

There may be sudden death; or there may be sudden pallor, syncope, and collapse, and the patient may live for some hours or even months.

Except in some traumatic cases in which surgical interference is possible, the outlook is hopeless.

The treatment is limited to immediate surgical operation in certain cases.

PNEUMOPERICARDIUM

Definition.—By pneumopericardium is meant the presence of air in the pericardial sac. It is a very rare condition. Pericarditis is always present, with serous (pneumo-hydropericardium), purulent (pneumo-pyopericardium), or hæmorrhagic (pneumo-hæmopericardium) effusion.

Ætiology and Pathology.—The affection may be due to wounds through the chest wall, or the result of communication with an air-containing organ or cavity, such as occurs in abscess or gangrene of the lung, pneumothorax, malignant disease of the œsophagus, gastric ulcer, and hepatic

Effusion of fluid, very frequently purulent, usually develops in the course of time.

Symptoms.—The onset may be sudden or gradual. Breathlessness, præcordial discomfort or even pain, faintness or syncope, and cyanosis are the most constant symptoms. There may be a certain amount of bulging of the præcordium; the apex-beat is diminished in force or even absent; on percussion, a tympanitic note is to be observed; and the cardiac sounds are diminished. On X-ray examination the air within the pericardium is evident.

If fluid is present the tympanitic area diminishes, and its site varies according to the position of the patient. In the recumbent position it may be heard over most of the præcordium, while if the patient be sitting upright the lower part of the præcordium becomes impaired and the upper part hyper-resonant. This is confirmed by X-ray examination. On auscultation, metallic and splashing sounds, resembling those produced by a water-wheel or a churn, synchronous with the movements of the heart, are audible; these sometimes become more pronounced on shaking the patient, and occasionally may be heard at a considerable distance. Pericardial friction is sometimes also to be noted.

Diagnosis.—The diagnosis is not difficult when the features enumerated are present. Care, however, should be taken to exclude a large pulmonary vomica in the neighbourhood of the heart, a left-sided pneumothorax, and dilatation of the stomach.

Prognosis.—The majority of cases die within the course of a few days. Traumatic cases, however, have been known to recover; the wound may heal and the air be absorbed.

Treatment.—In traumatic cases, paracentesis of the pericardial sac, with free incision and drainage if the fluid be purulent, is advisable. In other cases, treatment is usually palliative.

TUBERCULOSIS OF THE PERICARDIUM

Tuberculosis of the pericardium is not so rare as is generally supposed. It is usually secondary to tuberculosis of the mediastinal glands, the pleura, or elsewhere, but it may be part of a generalized tuberculosis, and some cases have been recorded in which apparently it was primary.

The morbid affection may be of the fibrinous type, ending in adhesions, which may be very thick; or it may give rise to effusion, varying from a small to a very large amount, in which event the membrane is often thickened and sometimes the fluid is hæmorrhagic.

In the case of fluid the onset may be slow and insidious. There may be pressure symptoms. The conditions may be recognised by percussion and X-ray examination.

In tuberculosis of the pericardium there may be, in addition to the usual symptoms, loss of weight and strength, and pyrexia.

A diagnosis may be made from an absence of rheumatism or other cause, the features described, and there may be evidence of tuberculosis elsewhere.

The fluid sometimes resolves spontaneously. The treatment is that of pericarditis together with that of tuberculosis.

FREDERICK W. PRICE.

OTHER DISEASES OF THE HEART OR PERICARDIUM

ANEURYSM OF THE HEART

Aneurysm of the heart may occur in its valves, or walls, or in the coronary arteries.

Acute aneurysm of the valves may occur in septic endocarditis, the semilunar being more commonly affected than the auriculo-ventricular valves. The aneurysm bulges in the direction of the blood current; rupture may take place, giving rise to perforation and valvular incompetence.

Acute aneurysm of the walls of the heart may take place in acute mural septic endocarditis, usually in the interventricular septum, in the neighbourhood of the undefended space. A diagnosis is scarcely possible.

Chronic aneurysm of the walls of the heart is comparatively rare. In the vast majority of cases it is the result of coronary occlusion with infarction of the heart (see page 991), but occasionally is due to fibrosis of the myocardium independent of such, and rarely to traumatism, the result of a stab, or to gummata.

In the majority of cases the anterior apical portion of the left ventricle is affected, or, less frequently, the aneurysm is found in the posterior wall of the left ventricle near the base. The aneurysm consists of a sac or localised depression, communicating with one or more chambers of the heart, the size varying from that of a small marble to an orange, or even larger. Its wall is formed of fibrous tissue and muscle-cells, in varying proportion,

according to the length of time it has been in existence. Occasionally a certain amount of calcareous matter is present. The endocardium is thickened and is often lined by laminated clot, which may give rise to emboli. The pericardium over the affected area is usually adherent.

The symptoms of aneurysm are those of general cardiac failure. The area of cardiac impairment may be increased, and occasionally a tumour in the region of the apex may be detected.

A diagnosis may be made from the history, the clinical features, and the results of X-ray examination.

Sudden death is not of uncommon occurrence, although rupture is comparatively rare.

Aneurysm of a coronary artery is rare and is usually due to atheroma.

WOUNDS OF THE HEART

Wounds of the heart are not of very uncommon occurrence. They may be the result of stabbing, bullet wounds, a paracentesis needle, or the passage of foreign bodies from the œsophagus. Recovery occurs in a fair proportion of cases, especially when due to stabbing. Treatment of these cases is purely surgical.

RUPTURE OF THE HEART

Rupture of the heart is a rare event, and recent observations suggest that in the great majority of cases it is the result of coronary occlusion with infarction of the heart (see above), but occasionally is due to fibrosis of the myocardium independent of such, and rarely to fatty degeneration or to traumatism. In the majority of cases the anterior apical portion of the left ventricle is affected, or, less frequently, near the base of that chamber or in the interventricular septum.

Rupture of the heart occurs nearly always during physical exertion. It may result in sudden death ; or its occurrence may be indicated by sudden agonising pain, intense dyspnœa, pallor, syncope, and collapse. In the latter case, the patient may live for some hours or even days.

CONTUSION OF THE HEART

This may result from the driver of a motor-car being thrown violently against the steering-wheel, or a very severe blow to the chest wall.

The symptoms and electro-cardiographic findings may resemble those of a coronary occlusion.

NEW-GROWTHS OF THE HEART AND PERICARDIUM

Neoplasms arising from the heart or pericardium are rare and relatively unimportant. Secondary neoplasms resulting from metastases from malignant disease elsewhere in the body, or from direct extension of malignant

disease of the œsophagus and lungs, are much more common than primary neoplasms, of which sarcoma and myxoma form the most frequent types.

It is seldom possible to diagnose neoplasms of the heart and pericardium before death. Radioscopy has permitted a diagnosis in rare instances. The prognosis is hopeless, and treatment by surgery or radiotherapy in the few cases recognised during life has been of little avail.

CONGENITAL HEART DISEASE

Ætiology.—Congenital heart disease is comparatively rare; it is found in about 2 per cent. of all patients suffering from organic morbus cordis. In the great majority of cases the condition is the result of some abnormality of development, but very occasionally a fœtal endocarditis would appear to be responsible. Heredity is probably a factor. The incidence is said to be relatively more frequent in first-born children. Some of the individual lesions are equally distributed among males and females, but in Maude Abbott's classical series, certain conditions, such as primary dextro-cardia, cor biloculare, cor triloculare and co-arctation of the aorta were found to be much more common in the male; and simple patency of the ductus arteriosus was more frequent in the female. The right side of the heart is more often affected than the left, and the pulmonary orifice very much more frequently involved than the tricuspid.

Other congenital anomalies are often present in congenital morbus cordis.

Varieties.—There are many varieties of congenital heart disease. A combination of several lesions is usually present, a single lesion being uncommon.

In ectopia cordis the heart is situated outside the thoracic cavity; it may lie in the neck (ectopia cervicalis) or outside the chest wall (ectopia pectoralis), or in the abdominal cavity (ectopia abdominalis). In meso-cardia, the heart occupies the mesial position of the thoracic cavity, the apex being in the epigastrium.

In dextro-cardia, the heart lies on the right side of the thoracic cavity, with the aortic and mitral orifices on the right, and the pulmonary and tricuspid orifices on the left, side. This variety of congenital heart disease is usually associated with transposition of the viscera. Dextro-cardia without transposition of other viscera is very uncommon, and when it occurs it is generally accompanied by some other cardiac lesion.

Defects of the pericardium may be met with.

Defects in the Interauricular Septum.—The foramen ovale is a valve-like opening between the auricles that during fœtal life allows the passage of blood from the venous to the arterial circulation without going into the lungs. It usually closes soon after birth and is generally completely impervious within a few weeks of life. The membrane closing the foramen ovale may, however, be defective at one point, leaving a valve-like slit, or it may be perforated by small fenestrations. Such changes may be observed in about one-fourth of all post-mortem examinations, and are not to be regarded as of any clinical importance. A widely patent foramen ovale may occur without other congenital abnormalities, but is generally associated with such lesions as pulmonary stenosis, or transposition of the great arterial

to divert most of the blood in the fœtus from the pulmonary artery into the aorta. It usually closes soon after birth. A patent ductus arteriosus is, however, a relatively frequent congenital lesion. It may vary in degree from a very fine passage to a comparatively wide canal. It may occur without any other congenital cardiac defect, but is more commonly compensatory to some such lesion. Thus, it may be associated with a pulmonary stenosis, in which case it serves to convey the blood from the aorta to the branches of the pulmonary artery; or with the congenital type of co-arctation of the aorta, in which event it will enable the aorta to be filled with blood from the pulmonary artery.

Congenital anomalies of the auriculo-ventricular valves occur very infrequently. In this connection, a considerable proportion of cases of tricuspid stenosis or atresia are congenital in origin, while tricuspid incompetence is rarely so, though it may be associated with pulmonary atresia. Congenital lesions of the mitral valve are much more rare than those of the tricuspid orifice.

Anomalies of the coronary arteries and of the great veins, and arteriovenous aneurysm are very rarely found.

Symptoms.—The subjective symptoms of congenital heart disease vary in intensity according to the site and degree of the lesion. Septal defects generally have a less disturbing effect upon the circulation than stenosis or atresia.

In congenital heart disease the symptoms are usually apparent soon after birth, but on the other hand nothing abnormal may be obvious until later on in life, and in some cases of septal defects the affection may be discovered only on physical examination or at necropsy.

Shortness of breath and cyanosis are the most common symptoms. The former is more frequent and may vary from a simple increase in the respiratory rate to extreme dyspnœa when cardiac failure is present. The degree of respiratory discomfort will depend upon the amount of oxygen unsaturation. Dyspnœa may occur in paroxysms during the time when there is a temporary increase in the amount of blood shunted into the systemic circulation, which in turn may lead to the occurrence or an increase of cyanosis. When there is marked dyspnœa, cough is common and hæmoptysis is not infrequent.

Cyanosis is found, in a slight to marked degree, in about half the cases; the term "morbus cœruleus" has, indeed, been applied to congenital heart disease. The cyanosis is in part due to the passage of unaerated blood directly from the right heart to the arterial system and in part to deficient oxygenation of the blood in the lungs, the latter the result of disturbances in the pulmonary circulation. Cyanosis will be seen in the skin and mucous membranes when the volume of reduced hæmoglobin in the capillaries rises above 7 per cent. It is usually most marked in the lips, nose, the malar region and the fingers and toes, being especially noticeable in the nails. It may be confined to these localities, or may be more general. The degree of cyanosis varies up to a deep purple, and is increased on exertion. The lips and nostrils may exhibit thickening, and clubbing of the terminal phalanges of the fingers and toes is usually present, due to chronic venous congestion. In cases showing cyanosis, the blood is found to have increased viscosity, and its specific gravity may be as high as 1070. There is a considerable

increase in the number of erythrocytes, and the number may occasionally reach 9,000,000 per cubic millimetre, and rarely even more. The hæmoglobin is also increased, and may be up to 160 per cent. The leucocyte count is unchanged, unless there is a complicating infection.

The temperature of the skin tends to be subnormal. The subjects of congenital heart disease are very susceptible to any fall of temperature, and are particularly liable to attacks of bronchitis. There is generally retardation of growth, and in many cases wasting. The mental condition is, as a rule, backward, and the patient is frequently dull and lethargic. As the result of anoxæmia, there may be syncopal attacks, which may even give rise to prolonged unconsciousness, while epileptiform attacks may also occur. There is a tendency to hæmorrhages from the nose and gums, and less often from the lungs.

The pulse may be quickened in rate. There is usually evidence of cardiac enlargement, of varying degree, the right side of the heart being especially affected. Frequently a murmur, and sometimes a thrill, usually systolic in time, are to be noted. While the point of maximum intensity of the murmur is commonly over the pulmonary area, it may be difficult or impossible to define. Usually the murmur is rough and harsh, and may be very loud, though it may be faint. The pulmonary second sound may be normal, diminished or increased in loudness. Distension or pulsation of the jugular veins may be present. The veins of the retina are dilated and tortuous, and both arteries and veins are much darker than normal. When there is marked congestion, retinal hæmorrhages may occur.

Other bodily malformations are not infrequently to be noted.

Indications of increasing chronic venous congestion, such as œdema, which at a later stage becomes general, hæmorrhages, hepatic enlargement, albuminuria, hæmoptysis and transudation of fluid into the serous sacs may supervene.

The chief complications of congenital heart disease are subacute bacterial endocarditis or endarteritis, one of the acute infective diseases, especially pneumonia and pulmonary tuberculosis, syncope, coma, convulsions, and hemiplegia, the result either of thrombosis or hæmorrhage. Paradoxical embolism may occur in subjects with a patent septum.

We will now pass to the consideration of the symptomatology of the individual lesions.

In dextro-cardia there is usually an absence of any subjective symptoms, and the lesion is only discovered accidentally, unless some other congenital abnormality causes symptoms. The apex-beat is on the right side of the thorax, and the point of maximum intensity of the aortic second sound is on the left instead of the right side. X-ray examination will reveal the condition. The other viscera are usually transposed, and if such is not the case, there is generally some co-existing cardiac lesion.

In uncomplicated patency of the interauricular septum when the defect is small, not infrequently there is an absence of subjective symptoms, and consequently the condition may not be discovered during life. In the case of a wide patency, the heart is enlarged, especially the right auricle and the right ventricle, which apparently receive additional blood from the left auricle. Systolic murmurs are present in about a quarter of the cases, and are best heard over the base or the midsternal region; and rarely a thrill has

been noted. Radioscopy may show enlargement of the right auricle and right ventricle, a prominent pulmonary arc and distension of the pulmonary branches.

When patency of the interventricular septum exists alone, *i.e.* Rogers's disease, the subjective symptoms may be slight. Cyanosis will not be present unless there is a veno-arterial shunt permitting one-third of the venous blood to pass through the septal defect from the right to the left ventricle. If the defect is large, the right ventricle will be hypertrophied. The characteristic signs of a patent interventricular septum are the presence of a systolic murmur, sometimes accompanied by a thrill, heard best in the third and fourth left intercostal spaces just to the left of the sternum, but it may be audible over the whole of the præcordium and both sides of the chest posteriorly. It is not conducted to the vessels of the neck. The intensity of the murmur will vary inversely with the size of the defect in the septum, and patients with loud murmurs may have no symptoms. In those cases described by Roger, the murmur commenced early in systole and was prolonged into diastole, and the point of maximum intensity was in the middle line over the upper third of the præcordial region. In patency of the interventricular septum, the second sound at the base in some cases is obscure, and in others is quite distinct. Usually there are manifestations of other congenital cardiac lesions, and these then predominate.

In congenital pulmonary stenosis, cyanosis is a feature in the vast majority of cases, because some other lesion is usually present. It is then noted within a few weeks of birth, but in rare instances may only make its appearance some years afterwards. Clubbing of the fingers, polycythæmia and defective growth are common. There is a harsh and loud systolic murmur, with its point of maximum intensity in the second intercostal space just to the left of the sternum, which may be audible over a considerable area of the chest and may be conducted upwards and outwards towards the left shoulder, but not to the vessels of the neck. There is often a systolic thrill. The pulmonary second sound is usually diminished or practically absent. X-ray examination is of considerable value in diagnosis. In cases of Fallot's tetralogy the cardiac apex is lifted away from the diaphragm, and there is sometimes concavity in place of the shadow of the pulmonary artery, but often the pulmonary arc is prominent. The ascending aorta is seen to pass up on the right side of the spine. The physical signs of congenital stenosis at the aortic orifice are the same as those of the acquired form of the disease.

The evidence of co-arctation of the aorta may be so slight that the lesion may entirely escape notice during life. The condition should be suspected when there is an inequality of blood pressure and pulse volume in the arms and legs respectively; the brachial systolic blood pressure may be considerably raised, even up to 200 mm. or more, while the femoral blood pressure is low, 100 mm., and the femoral pulse is small. The pressure in both arms is generally equal, except in those infrequent cases in which the co-arctation occurs proximal to the origin of the left subclavian artery. There is evidence of a compensatory collateral circulation, and the internal mammary, intercostal, scapular and deep epigastric arteries may be dilated and tortuous. A long systolic murmur, rarely accompanied by a thrill, may be heard over the aortic area and præcordium, and the murmur may be transmitted along the course of the dilated anastomosing vessels. X-ray examination will

show enlargement of the left heart, while there is a decrease or an absence of the shadow of the aortic knob with dilatation of the ascending aorta and the first part of the aortic arch. Erosion of the ribs by the dilated intercostal arteries may be seen. Marked co-arctation of the aorta may lead to heart failure, while rupture of the aorta, apoplexy due to cerebral hæmorrhage, and an infective endarteritis invading the area of the co-arctation may occur.

Hypoplasia of the aorta may be accompanied by a tendency to pallor, with slow and incomplete growth and a generally backward development.

When a patent ductus arteriosus occurs alone, there may be an absence of subjective symptoms. In other cases, there may be shortness of breath and slight cyanosis. When the lesion is compensatory to some associated congenital abnormality, such, for example, as a pulmonary stenosis, shortness of breath and cyanosis may be marked, and the patient is often under-developed. Characteristic of a patent ductus arteriosus is the presence of a murmur with certain features. Its point of maximum intensity is in the second left intercostal space close to the sternum. It may be systolic in time but usually is continuous during systole and diastole, beginning shortly after the commencement of the first sound and extending into a considerable part of diastole and it may be persisting throughout the cardiac cycle, frequently with systolic accentuation. The murmur is loud and harsh. It has variously been described as resembling the sound of a humming-top, or a mill-wheel. It is well conducted towards the left clavicle, but is not propagated downwards to the right or into the carotid arteries. There is generally a thrill. The second sound in the pulmonary area may be accentuated. Enlargement of the right ventricle and the conus arteriosus will tend to occur, and X-ray examination will show an abnormal bulging of the left upper border of the cardio-vascular shadow. As was pointed out by Gerhardt, the area of cardiac impairment may extend unduly to the left of the sternal border. In exceptional cases the patent ductus arteriosus may be the seat of an aneurysmal dilatation.

For Clinical Electro-cardiography in Congenital Heart Disease, see p. 1007.

Diagnosis.—While it is usually not difficult to say that congenital heart disease exists, the diagnosis of the variety is often fraught with great difficulty because of the frequent combination of defects and the variability of the physical signs.

In considering the question of diagnosis, the history of the case, the subjective symptoms, the existence or otherwise of evidence of enlargement of the right side of the heart, and the time of occurrence, the point of maximum intensity and the direction of selective propagation of any existing murmur, are all points which should be taken into account. X-ray examination may furnish valuable information with regard to differential diagnosis.

With regard to the diagnostic value of the various symptoms, it may be remarked
attack
anæmic and rickety subjects,
the fingers may exist in the acquired form of heart disease, more especially in mitral stenosis, while it may be absent in the slighter forms of congenital disease. It is also necessary to point out that in some cases of congenital

heart disease the right side of the heart may be only slightly enlarged. The murmurs are usually systolic in time, and loud, and their point of maximum intensity and direction of selective propagation are not so typical as those of the acquired form of heart disease. In cases of a non-functional systolic murmur, having its point of maximum intensity over the pulmonary area, the possibility of congenital heart disease should be thought of. It may, however, be exceedingly difficult, and indeed impossible, to distinguish functional basic murmurs from those of congenital heart disease during infancy and childhood by means of auscultation alone, though such murmurs are usually not so harsh as those due to congenital defects, and are not accompanied by cardiac enlargement or cyanosis. It should be recognised that a continuous murmur occupying systole and diastole may also be due to a venous hum transmitted from the neck as well as to arterio-venous aneurysm.

If there be a history of a marked cyanosis soon after birth, and of the presence of clubbing of the fingers, evidence of enlargement of the right side of the heart, and a systolic thrill and murmur whose point of maximum intensity and direction of selective propagation are not so typical as those of the acquired form of heart disease present in early life, a positive diagnosis of the congenital form of heart disease is not difficult. The discovery of congenital anomalies elsewhere in the body favours the diagnosis of congenital heart disease.

With regard to the differential diagnosis of the variety of the lesion or lesions, the reader is referred to the section on Symptoms, pp. 970–973.

Prognosis.—The prognosis of congenital heart disease exhibits wide variation. If the defect be slight, as, for example, a patent foramen ovale or a small opening in the interventricular septum, a considerable proportion of cases may live to an advanced age without experiencing at any rate pronounced subjective symptoms. Even in these cases, however, there is a liability to bacterial infection, especially of a streptococcal nature. Such is by no means infrequent, particularly in the case of bicuspid aortic valves and a patent ductus arteriosus, and is of serious significance, being always fatal. If the defect is severe, the prognosis is more serious. In a large proportion of cases the duration of life is brief and, indeed, the individual may die a few hours after birth. According to Paul White, the prognosis depends upon two factors: (1) The degree of anoxæmia, which is indicated to a certain extent by the degree of cyanosis; and (2) the amount of direct strain on the heart. It should be remembered that anoxæmia and cyanosis are not strictly comparable, for if there is a polycythæmia there may be a sufficient quantity of oxygen in the blood for the tissues, and yet there may in addition be enough reduced hæmoglobin to cause the cyanosis. Lastly, the prognosis is much influenced by whether the patient is well protected against an unfavourable environment and intercurrent disease.

Ectopia cordis is rarely compatible with extra-uterine life. Meso-cardia, dextro-cardia and defects of the pericardium are compatible with long life. Life cannot exist with a bilocular heart. Trilocular heart is compatible with life for some years, and, indeed, instances have been recorded in which individuals have lived to adult age; usually, however, the period of life is short. Persons suffering from septal defects not infrequently live to an advanced age. When patency of the interventricular septum occurs alone

and the opening is not large, the individual may live to past middle life; when it occurs in association with other lesions, the prognosis depends upon the latter. The prognosis of an individual suffering from pulmonary stenosis depends upon, besides those points already mentioned, whether there is a patent interventricular septum to afford relief to the over-distended right heart. Death may occur, on the one hand, within a few hours after birth, while, on the other, in the case of lesions of slighter grade, life may be prolonged for 5, 10 or 20 years, and occasionally even to middle life; indeed, if a patent interventricular septum be present in these slighter lesions, cases have been recorded in which patients have lived to the age of 60. Taking cases of pulmonary stenosis as a whole, however, most of the patients die at an early period of life. Pulmonary atresia is a much more serious condition, and life is prolonged for only a brief period. Cases of stenosis at the aortic orifice very rarely survive birth, and in those in which stenosis exists above the entrance of the ductus arteriosus, life is prolonged at the outside for a few months only, but when just below the entrance of the duct it may be prolonged till middle age or over. Cases of transposition of the great vessels do not survive for more than a few hours unless there is a septal defect, in which case they may live for some years, and instances up to adult or even middle age have been recorded. Persistence of the ductus arteriosus is not infrequently compatible with adult life, and individuals have been known to have lived even to old age.

Treatment.—The general measures previously laid down are applicable also to this affection. It is particularly important that the patient should be kept warm, and it is imperative that careful and detailed measures should be adopted for the prevention of bronchitis; if bronchitis should occur, adequate treatment should be adopted without delay. Even in the least serious lesions, care should be taken to guard against infection. When the tonsils are diseased, tonsillectomy is advisable in childhood if the risk is not unreasonable, but not during infancy.

If cardiac failure supervenes, or if any complication occurs, they are to be treated on the lines laid down elsewhere.

SYPHILITIC AFFECTIONS OF THE AORTA, THE HEART, AND THE PERICARDIUM

This subject is one of much importance and also of considerable difficulty, more especially as regards the relative frequency and diagnosis of the condition, which are intimately bound up with ætiological and pathological considerations. I shall confine my remarks to the acquired form of the disease.

Relative Frequency and Pathology.—Formerly the importance of syphilis as a cause of heart disease was not sufficiently recognised. Later the pendulum swung too much the other way. Thus, assertions that syphilis is responsible for a quarter to one-third of the total number of cases of organic disease of the heart, for about three-quarters of all cases of aortic incompetence and almost invariably for those in which there is an absence of a definite history of acute or subacute rheumatism, and is by far the most frequent cause of chronic myocardial disease are quite unwarranted.

As to the first, statistics vary exceedingly, but it is probable that syphilis accounts for less than 10 per cent. of all cases of organic heart disease in this country, though its incidence is higher in some non-European populations; it is the cause of about one-third of all cases of aortic incompetence and accounts for a considerable majority of those occurring between the ages of 40 and 60, especially in males; and is an important ætiological factor of angina pectoris under the age of 40. There is good reason for the belief that syphilis as a cause of heart disease is diminishing. Excluding the possible effect of the present war, it is much more often responsible for such in males than in females.

Syphilitic arteritis commences in the secondary stage but may only become marked in the tertiary.

Acquired syphilis may affect the aorta, which may involve the orifices of the coronary arteries; in the opinion of some writers, very rarely the coronary arteries themselves; the cardiac valves; and the myocardium.

The pathology of syphilis of the aorta (syphilitic mesaortitis) and its results are described on page 1031, and elsewhere.

The following considerations are among those noted: The first part of the aorta is the most commonly affected. Syphilis invades the aorta from without. The disease-process is the result of inflammation of the vasa vasorum and their terminations in the coats of the aorta. The adventitia and, later, the media of the areas of the aorta supplied by the inflamed vasa vasorum are secondarily affected, and the inflammation is mainly confined to these coats. The inflammation in the media is followed by absorption and, it may be, necrosis of the elastic tissue and muscle-fibres, and at a later date by new formations of fibrous tissues. The intima over the areas of inflammation is usually thickened. This is merely secondary, and is protective or compensatory. In its earlier stages, it is to be distinguished from atheroma by the naked eye. It is to be added, however, that in the later stages, atheroma usually occurs in the thickened intima over the areas of inflammation; also that syphilitic mesaortitis and primary atheroma may co-exist, especially in later life.

The weakening of the middle coat of the aorta by syphilitic aortitis leads to dilatation of its lumen. This may be general (diffuse aneurysm), or localised (circumscribed or saccular aneurysm); the latter is usually accompanied by some degree of the former.

Syphilitic aortitis may give rise to narrowing or complete occlusion of the coronary arteries (see p. 948). As stated, in the opinion of some, syphilis may rarely affect the vessels themselves. The disease-process in the aorta may spread to the aortic cusps, giving rise to incompetence of the valve (see p. 932), and in the opinion of some it rarely extends to the base of the aortic cusp of the mitral valve. Syphilis may cause fibrosis of the myocardium, (see p. 949). Gummata are relatively rare. The commonest site is in the septum, especially high up, and in the case of the latter the conducting system may be implicated and auriculo-ventricular block may result, but they may also occur in the wall of the heart.

In congenital syphilis, spirochætes are frequently numerous throughout the myocardium, but the latter usually shows little change although in some there is a good deal of proliferation of the connective tissue. Gummata may also be met with.

Symptoms.—Most patients do not consult a doctor for cardiac symptoms before 15 to 25 (usually about 20) years after the primary infection, whereas in the great majority of cases the aorta has been affected long before this.

The symptoms of syphilitic aortitis depend upon the extent of the lesion, that is, whether there is involvement of the coronary arteries, general dilatation of the aorta, aortic incompetence, implication of the myocardium, or saccular aneurysm.

The most common early symptoms are dyspnœa on exertion; oppression, discomfort or pain in the front of the chest, usually in the upper sternal region; and paroxysmal dyspnœa. It is important to recognise the characteristic features of the pain. It is often localised but may radiate to the arms and neck. Its degree may vary from slight to severe. It may come on spontaneously, *i.e.* apart from physical exertion, especially on lying down, in which event it may be intermittent or constant, and is generally aggravated by exertion; or it may occur only on exertion, in which case it may continue after the cessation of effort. There may occasionally be hyperæsthesia over the painful area. Severe paroxysms of dyspnœa, including nocturnal, are not infrequent. There may be paroxysmal pain together with paroxysmal dyspnœa while at rest. Sometimes a moderate or faint systolic murmur and an accentuation of the second sound, the latter of which may be of low pitch, in the aortic area are present. Some observers are of opinion that rubbing sounds along the right border of the sternum may be noted, especially when the patient leans forward; personally I have never been able to detect such. The foregoing manifestations may disappear after a few months or weeks, either spontaneously or the result of treatment.

The subsequent course and presentation vary very considerably. The latter may include general dilatation of the aorta; aortic incompetence; angina pectoris; involvement of the myocardium; pulmonary and systemic venous congestion; and saccular aneurysm. In the first, there may be pulsation in the suprasternal notch; not infrequently a systolic murmur and a modification of the second sound in the aortic area as described; and rarely impairment of percussion note over the manubrium sterni and on either side of it. For the results of X-ray examination, see below. Aortic incompetence may develop insidiously or otherwise. Involvement of the myocardium may reveal itself on electro-cardiographic examination by the presence of auriculo-ventricular block, or rarely by bundle-branch block, intraventricular block, or paroxysmal or persistent auricular fibrillation. If congestive failure occurs, it is usually progressive and may be rapidly so. As regards saccular aneurysm, see elsewhere. Sudden death is by no means rare. Subacute bacterial endocarditis may supervene. Lastly, relative or even complete recovery—either the result of specific treatment or spontaneously—may occur at any period.

X-ray examination may reveal general dilatation (Fig. 44), or saccular aneurysm, or both, of the aorta. With regard to the former, as the first part of the aorta is most commonly affected, the commonest X-ray finding is increased convexity of the right border of the supra-cardiac vascular shadow just above the right auricle. There may, in addition, be enlargement of the shadow to the left in the region of the aortic knob. Occasionally the descending thoracic aorta is affected. There may be also increased density of the shadow. If a saccular aneurysm projects mainly backwards, the

shadow of the sac, when viewed from the front, may be within that of the aortic shadow itself. In such a case, rotation of the patient to the right or left will enable the observer to separate the shadow of the sac from that of the aorta. In saccular aneurysm, there is usually also some degree of general dilatation. In syphilitic aortitis, there may be also the characteristic changes in the aortic shadow of co-existing atheroma, especially in later life. If there is aortic incompetence, the enlargement of the left ventricle is shown by extension of the heart to the left and increased convexity of the left border, and the latter may exhibit exaggerated pulsation.

In the early stages the Wassermann or other serum reaction is almost invariably positive, but as the disease becomes more chronic it is increasingly negative, although the frequency with which a positive Wassermann persists even in the case of patients who, clinically, have done well is surprising.

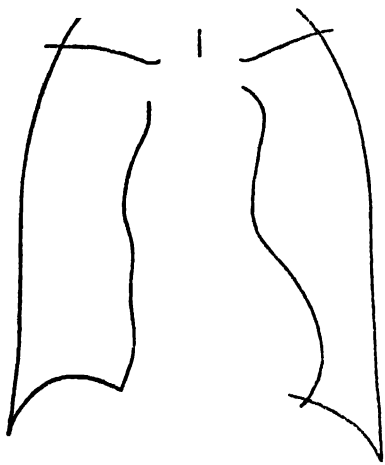

FIG. 44.—Orthodiagram from a case of aortic incompetence, of syphilitic origin. The left ventricle is moderately enlarged, and the aortic shadow is generally enlarged, especially on the right side.

Diagnosis.—The following should be considered: Whether a previous history of a rheumatic or syphilitic infection; the subsequent history; the age; the clinical picture; the results of X-ray and electro-cardiographic examinations, the first being much more important; the Wassermann or other serum reaction; and the presence or otherwise of syphilitic stigmata.

It is easy to overlook a rheumatic infection in childhood; and there may be a history of both rheumatic and syphilitic infection in the same patient. Rheumatic disease usually reveals itself in early life; syphilis generally in middle life; while a cardiac affection coming on in the elderly is commonly the result of primary degenerative processes. A cardiac malady between the ages of 40 and 60, in the absence of hypertension and hyperthyroidism, is very suggestive of syphilis. Syphilis is an important cause of angina before the age of 40.

The early manifestations of aortitis have been described. The pain

differs from that of angina pectoris in that its location is higher; it has far less tendency to radiate to a distance; it is more likely to come on spontaneously, and to be persistent; and if related to physical exertion, not to disappear on the cessation of such. Paroxysms of dyspnœa are very suggestive. A combination of aortic and mitral valvular disease, especially before 30 years of age, points to a rheumatic origin. Aortic incompetence alone, *i.e.* without stenosis and mitral disease, occurring between the ages of 40 and 60 is in a considerable majority of cases due to syphilis, especially in males. It is to be noted that sometimes a combination of valvular lesions the result of both rheumatic and syphilitic infection is occasionally met with.

X-ray examination is of supreme value in all stages of the disease, and the frequency with which the early stages are overlooked could, in large measure, be remedied if all those with a history of syphilis were from the outset periodically examined by this method for evidence of aortitis. The results of X-ray examination have been described. It is necessary to distinguish between general dilatation due to syphilis from that caused by atheroma, or hypertension, or both. This is dealt with on p. 996.

A serological test should be done in all doubtful cases. A negative is not so valuable as a positive reaction; a single negative does not exclude syphilis; and in some cases it may be advisable to employ a provocative dose of one of the organic arsenical preparations. We should, on the other hand, be careful not to place too much reliance on the result of the serum test; it should be considered in conjunction with other data. Lastly, a positive reaction does not indictae that the patient is necessarily syphilitic; and the same applies to the coexistence of other specific stigmata.

Prognosis.—This depends largely upon early diagnosis and the kind of treatment adopted. Taking cases as a whole, the prognosis is very unfavourable, in all probability owing to the fact that a correct diagnosis is not often made until the later stages of the disease. When untreated, the lesion is usually progressive, it may be rapidly so, and the mortality is high. If, on the other hand, a diagnosis is made early and treatment is prompt and suitable, there is a reasonable prospect of relative recovery, and not infrequently recovery is even complete. Naturally the prognosis is much more favourable in the absence of saccular aneurysm, angina pectoris, congestive failure, and aortic incompetence, especially the first three. The first is discussed elsewhere. Even in the absence of angina pectoris and aneurysm, in aortic incompetence the prognosis is generally very unfavourable, death often taking place within two or three years after the onset of symptoms. Congestive failure in syphilitic aortitis is particularly unfavourable, rarely responding to treatment, and it is improbable that such cases will live for more than six months. The results of electro-cardiographic examination are sometimes helpful. Lastly, in all types of cases, surprising improvement is occasionally met with when suitable specific treatment is adopted.

Treatment.—The question whether a preliminary rest is required, and, if so, how much should first be considered. I would add that even in the absence of obvious manifestations of cardiac failure a rest of four to six weeks is an advantage. The various measures which may be applicable to any from of cardiac disorder should be reviewed in detail. See pp. 861–875. Apart from these considerations, the indication is for anti-specific treatment, even in the absence of a positive serum reaction. This should be prompt,

suitable, and prolonged. I am a firm believer in the employment of the arsenical organic preparations, not excluding cases of angina pectoris and congestive failure, but only under certain conditions, as set forth below. Their indiscriminate use is attended with danger, even of grave degree; they may give rise to a focal reaction and consequent increased involvement of the orifices of the coronary arteries.

The scheme I recommend is the result of some conversations I have had with Col. L. W. Harrison, to whom I desire gratefully to acknowledge my indebtedness.

It is always advisable to begin treatment with bismuth or mercury, preferably the former. A very useful preparation for the first course is the iodo-bismuthate of quinine (see pp. 218, 219), which contains approximately 20 per cent. of the metal. A suitable course would be 20 intramuscular injections of the 10 per cent. emulsion, in doses of 3 or 4 c.c. twice weekly, the course lasting approximately 10 weeks. Alternatively, the iodo-bismuthate may be administered for 10 injections and the course be completed with 5 injections of a compound with a higher content of bismuth metal, such as the oxychloride (see pp. 218–221), which contains 80 per cent., at weekly intervals. In this case the weekly injection from the fifth week would be such as contained 0·16 to 0·24 g. bismuth metal. Another alternative is to give from the start a course of 20 injections of an oil-soluble preparation (see pp. 217–221) in doses of 2 c.c. twice weekly. For further details of bismuth preparations, their choice and the technique of their administration see pp. 217–221. Throughout it is important to keep a close look out for evidence of irritation of the kidneys. Any sign that the bismuth is producing this would be an indication to suspend the remedy and resume, with a smaller dose, only when the signs of irritation had disappeared.

Concurrently with the injections, potassium iodide should be given in doses of 15 grains thrice daily.

A month after the end of the first course a second one should be commenced, and continued until 10 injections of an insoluble compound of bismuth each containing 0·16 to 0·24 g. bismuth metal, have been given at weekly intervals. During this course, provided that there is no contra-indication in angina pectoris or congestive heart failure, a cautious start may be made with one of the arsphenamine preparations, either sulpharsphenamine (kharsulphan, metarsenobillon, myosalvarsan, sulfarsenol, or sulphostab) intramuscularly, or neoarsphenamine (neoarsphenamine-Evans, neokharsivan, neosalvarsan, novarsan, novarsenobillon, or novostab) intravenously twice weekly, in such doses as the following: $2\times0{\cdot}10$ g., $4\times0{\cdot}15$ g., $4\times0{\cdot}30$ g., and $10\times0{\cdot}45$ g. For technique of injection of the arsphenamine preparations see pp. 210–214.

It is important in administering arsphenamine preparations to these cases to avoid general reactions. These are more common after intravenous than intramuscular injection and after rapid than slow injection. Any general reaction is an indication to reduce the next dose to the minimum with which the course was started, and, if it is repeated, the administration of the arsphenamine preparation should be suspended.

If the arsphenamine preparation has been well tolerated, in the third course, commenced 6 weeks after the end of the second, it may be given once weekly concurrently with a weekly dose of an insoluble bismuth pre-

paration, the total injections of each type of remedy being 10. Following the third course, mercury and iodide may be administered by the mouth for about three months, and afterwards the specific treatment be continued as recommended for cases of latent syphilis on p. 223.

ANGINA PECTORIS

General Considerations.—The subject of angina pectoris is of much practical importance, more especially as regards diagnosis and the management of a case. Thus, in my experience, the malady is frequently overlooked and, moreover, many patients die many years earlier than need be.

At the outset it is of cardinal importance to understand what is meant by the term. Angina pectoris is a symptom-complex, which may be associated with a diversity of cardio-vascular organic disease, and may even be independent of such, *e.g.* severe anæmia. It is characterized by paroxysmal attacks of pain, in the great majority of cases in the front of the chest, most commonly in the retrosternal region, with a tendency to radiate in certain directions; frequently accompanied by a sensation of oppression or constriction; or, occasionally either of these sensations without pain; and the exciting cause of the first attacks is in the great majority of cases physical exertion.

Ætiology, Morbid Anatomy, and Pathogenesis.—Heredity is, in my opinion, certainly a factor, one of the reasons for this being that cardio-vascular degenerative changes are more prone to occur in certain families. The malady is found more frequently in those who are passing from middle into elderly life; if syphilis is the cause, not infrequently earlier; while in aortic incompetence the result of antecedent acute or subacute endocarditis it may be met with in the third or even the second decade. It is much more common in those classes of society who are subject to excessive mental or emotional stress or strain, being relatively uncommon in those whose occupation is of a manual character; in which connection, I am of opinion that mental and emotional stress and strain are undoubted, if not potent, causes of atheroma of the coronary arteries. It is more likely to occur in individuals with an unduly sensitive nervous system. Other predisposing causes are those of atheroma (see p. 1038); hypertension; syphilis; acute and subacute rheumatism; and occasionally one of the other acute infective diseases, particularly influenza and enteric fever. In syphilis the disease-process involves the orifices of the coronary arteries, or gives rise to aortic incompetence.

The most common structural changes are disease of the coronary arteries, disease of the aorta, aortic incompetence, especially of syphilitic origin, and chronic myocardial disease, the last usually the result of coronary disease. By far the most common is atheroma of the coronary arteries. There may be old infarcts in the myocardium.

In coronary disease there may be, in addition, spasm of the vessels. It is believed that the attacks are sometimes induced by spasm of the vessels even in the absence of organic disease. Angina occasionally occurs in aortic regurgitation, generally due to syphilis. It is rarely met with in paroxysmal tachycardia (or paroxysmal auricular flutter with a very rapid ventricular

rate or paroxysmal auricular fibrillation with a very rapid ventricular rate), thyrotoxicosis, and in severe anæmia, independent of organic cardio-vascular disease.

Among the exciting causes of the attacks are physical exertion, emotional excitement of any kind, mental effort, cold, such as exposure to a cold wind or atmosphere, and cold sheets, the ingestion of food, and dyspepsia, particularly attended with distension of the stomach or colon. There may be a combination of two or more factors. Thus, an attack is more likely to occur during physical exertion after a meal. An extreme example is hurrying uphill on a cold day against a strong wind and engaging in an excited conversation soon after a full meal. Physical exertion is much the most frequent exciting cause, and in the first attacks is so in the great majority of cases. In the case of physical exertion the attacks almost always occur *during* it; in that of emotional excitement, usually so; and in that of mental effort, generally *afterwards*.

Angina pectoris sometimes follows coronary occlusion. Again, the same individual may at one time suffer from angina and at another from coronary occlusion.

It is to be observed that angina pectoris rarely affects those with congestive heart failure or auricular fibrillation. Moreover, if either of these supervenes in those suffering from angina pectoris, usually no further attacks occur.

The hypotheses which have been advanced as to the actual cause of the attack include the following:

The current view, which is probably correct, is that the attack is due to transient relative anoxæmia of part, or less frequently the whole, of the myocardium. The supply of oxygen is insufficient for the demands made upon the heart muscle. The greater the degree of anoxæmia the more easily is an attack induced. The anoxæmia is in the vast majority of cases due to inadequacy in the amount of arterial blood supplied to the myocardium. In the great majority of these this is the result of structural disease of the coronary arteries. It is believed that it may be caused by functional spasm of the vessels. In aortic incompetence, there is a diminished coronary circulation due to the low diastolic pressure. In paroxysmal tachycardia, the shortening of the diastolic period also gives rise to a diminished coronary circulation. Thyrotoxicosis makes an excessive demand on the circulation. In severe anæmia the smaller hæmoglobin content results in a deficiency in the carrying power of the blood, *i.e.* the anæmic type of anoxæmia. Lastly, an attack can occur when there is a diminished oxygen saturation, *i.e.* such as obtains at a high altitude or in a partially exhausted chamber. In support of the anoxæmic origin of angina pectoris, the following may be mentioned. The pain of angina resembles that of coronary occlusion; transient changes in the electro-cardiogram similar to those of coronary occlusion have been noted during the attacks in some cases; and experimentally induced anoxæmia in the subjects of angina has in some brought on attacks of pain and, in some, transient changes in the electro-cardiogram.

The late Sir Clifford Allbutt regarded the phenomena as generally, but not always, produced by tension of the first part of the aorta, which is the seat of some inflammatory or degenerative lesion. He described certain rarer cases in which the morbid stress falls on the pericardium. He was

of opinion that the relief of pain by nitroglycerine was due to dilatation of the peripheral arteries and a diminution of the blood pressure in the aorta; and that sudden death, when it occurs, is the result of "vagus inhibition," the shock of the pain causing asystole, associated with myocardial and coronary disease, which is so frequently found in the subjects of angina. Wenckebach believed in the aortic origin of the attack in the majority of cases. The late Sir James Mackenzie's views were the following: That angina pectoris is an expression of exhaustion of the heart muscle, together with a susceptible nervous system. The pain is a viscero-sensory reflex; the sense of constriction a viscero-motor reflex, giving rise to spasm of the intercostal muscles. That sudden death is due to the lesion causing the pain, and is frequently the result of ventricular fibrillation. Other hypotheses are that the attack may be due to neuralgia of the cardiac nerves; or to cramp, or spasm, of the heart; or to distension of an enfeebled left ventricle.

In conclusion, it should be noted that the precise actual cause of the attack is not at present fully understood. While the anoxæmic origin may be accepted in the majority of cases, this does not exclude the possibility of the pain of angina arising in the aorta, as suggested by the late Sir Clifford Allbutt, in certain cases.

THE VARIETIES OF ANGINA.—Various methods of classification are employed by different writers, among which are the following: (1) Angina minor and angina major; (2) primary and secondary angina; (3) true and false or pseudo-angina; (4) angina of effort (or exertion) and angina at rest—the latter being sometimes called angina of decubitus; and (5) angina of effort and angina of coronary occlusion with myocardial infarction.

The first, in my opinion, serves no useful purpose. For angina may range from pain which is slight to that which amounts to anguish; between these two extremes there is an almost infinite variety in the severity of the attacks; there is no approximate line of demarcation between the two forms; and the same individual may experience attacks of considerable or even great variation at different times. Respecting the fourth, it is to be observed that the subjects of angina at rest almost always also suffer from angina of effort.

The last classification of angina, *i.e.* angina of effort and that of coronary occlusion rests upon the fact that in both the locality and distribution, and the character of the pain are similar; in the opinion of most, but be it noted not of all, the cause of the pain is the same, *i.e.* anoxæmia of the myocardium; and transient modifications of the electro-cardiogram resembling those of coronary occlusion have been observed in some cases of angina during the attacks. I am of opinion that this classification is fundamentally erroneous, for the following reasons: (1) In angina pain constitutes almost the whole clinical picture, whereas in coronary occlusion it is only a part and, moreover, the component parts of the clinical picture are usually very unlike. A careful comparison of the clinical features outlined on pp. 984, 985 and pp. 991, 992 respectively will readily reveal the foregoing. (2) Pain (or a sensation of oppression or constriction) may be absent in coronary occlusion. (3) As has been pointed out, angina may be associated with a diversity of cardio-vascular organic disease, and may even be independent of such; whereas in occlusion there is a uniformity of the pathological condition. (4) In angina there is a relative and transient anoxæmia, whereas in occlusion the blood

supply is completely and permanently cut off, and that part of the wall of the heart is permanently destroyed. (5) The appropriate therapeutic measures are very different.

The best classification, in my opinion, is (1) angina associated with organic cardio-vascular disease, and (2) that which is independent of such. The latter may occur in paroxysmal tachycardia, thyrotoxicosis, severe anæmia and, it is believed, functional spasm of the coronary arteries.

Symptoms.—The exciting causes of the attacks have been described. It is to be noted that an attack may exceptionally occur during rest and even during sleep.

Paroxysmal pain is the cardinal feature. Its onset is usually sudden, it increases rapidly in severity, and subsides more or less gradually. Its degree may vary from slight discomfort to that of intense anguish. In the great majority of cases, the pain is situated in some part of the front of the chest. It occurs most commonly in the retrosternal region; next, across the front of the chest; sometimes on either side of the front of the chest, more often the left; not infrequently in the epigastrium or lower in the abdomen—the so-called angina abdominis; rarely in the back of the chest; and more rarely in any of the areas to which pain arising in a more common site may spread (see later). The pain has a tendency to radiate in certain directions; frequently to the left shoulder and armpit; in many cases down the left arm, generally on the ulnar side, usually not beyond the elbow, but it may extend as far as the tips of the ring and little fingers; sometimes both arms; occasionally the right arm only; to near the angle of the scapula, on one or both sides, or to a wide area in the back of the chest; in an upward direction, to the infra-clavicular region, the neck, the jaw, especially the left, the occiput, or even the top of the head; or in a downward direction, to the abdomen, or even to the lower extremities. When the locality of the pain is in an area to which that arising in a more common site may spread, it may or may not radiate. As a general rule, the more severe the pain, the more frequently does it radiate and also the wider the radiation.

The pain is frequently accompanied by a sensation of oppression or constriction, and the latter may be so severe that the patient experiences a sensation as if the chest were held in a vice. Occasionally there is oppression or constriction without pain. Instead of pain, or a sensation of oppression or constriction, the patient may complain of a sensation of rawness or of burning in the front of the chest. There may be a sensation of weight or of tingling or numbness in the left arm. The breathing is generally restricted, and its rate is only infrequently increased. If the patient is in motion, usually he becomes immobile and remains so, and with a cessation of effort, the pain quickly subsides. Sometimes, however, he is able to continue his effort without pain. If the pain is at all severe, it is often accompanied by a sensation of anxiety out of proportion to its severity and, if still more severe, occasionally by a sense of impending dissolution—angor animi. It is believed by some that very rarely a sense of impending dissolution occurs alone, *i.e.* without pain—the *angina sine dolore* of Gairdner.

The expression of the face may be anxious. The skin may be pallid, and there may be a clammy sweat, but occasionally the opposite is the case. There may be flatulence, nausea, occasionally vomiting, and very rarely hiccough. The pulse-rate varies in different cases; in some it is increased,

while occasionally it is diminished. The blood pressure is generally increased to some extent during the attacks. The cardiac sounds may be weak. There may be irregularity of rhythm, usually due to extra-systoles.

The duration of the attack may vary from a few seconds to a few minutes or longer, the average being a few minutes, and even severe attacks rarely last much longer.

The term status anginosus is applied to prolonged attacks of pain, periodically increasing and diminishing, or a series of attacks, which are practically always due to coronary occlusion.

The severity of the attacks may vary from pain or a sensation of oppression or constriction or rawness or burning, each only of slight degree and lasting for a few seconds, to pain which amounts to anguish. The locality and distribution of the pain and how it is induced are of much greater significance than its variety.

As the attack subsides, the patient may belch up a large quantity of air, and it is often followed by the passage of abundant pale urine. After the attack there may be exhaustion, aching in the area of the pain, a sensation of weight, or of tingling or numbness in the left arm, and hyperæsthesia or hyperalgesia over the painful area, even for some time. On the other hand, it is surprising how soon the patient may be free from symptoms, even after a severe attack.

In the early stages the attacks may be related only to the more severe forms of physical exertion, and the same applies to other exciting causes; the symptoms may be only mild; the pain may not radiate; the attacks may be very brief; and the symptoms may disappear as soon as the exciting cause ceases. As the malady progresses, the attacks tend to become more and more easily induced, so that they may occur when the patient is walking at the ordinary rate or even slowly on the level, or even during the act of eating; the symptoms tend to become more severe; more frequently does the pain radiate and also over a wider area; the duration of the attacks is increased; and the symptoms last longer after the exciting cause ceases. Ultimately the attacks may appear to be independent of any obvious exciting cause. In this connexion, however, it is necessary to point out that in at least a considerable proportion of these cases such is really not the case, for, on careful inquiry, it will be found that they occur when the patient is tired, it may be some time after an exciting cause. On the other hand, the first attacks may be severe; the severity of the attacks may alternate; and the attacks may become less severe and even cease, either as the result of treatment, or spontaneously.

Death may occur during or after an attack, the result of ventricular fibrillation, or, less frequently, of coronary occlusion.

Diagnosis.—This may be very difficult when the symptoms are slight and there is an absence of evidence of cardio-vascular disease, particularly in the case of the former. Nevertheless, if all the avenues of investigation be fully taken advantage of, a correct opinion is possible in the great majority of cases. The following points, among others, require consideration: the age; the sex; the history of the patient's complaint; and the results of examination, this including by the X-rays and the electro-cardiograph.

The history of the patient's complaint is of pre-eminent importance, and is of infinitely more value than what is found on clinical and instru-

mental examination—indeed, there may be a complete absence of abnormal findings in the subjects of undoubted angina pectoris. It follows, therefore, that a searching and detailed inquiry of the patient's complaint, from its inception, should be made. The characteristic features of the pain and concomitant symptoms, together with the existence and nature of the exciting cause, have been described so fully that all that is needed is to refer the reader to such for his careful consideration. The following may be added: A noteworthy feature is that, in the same individual, excepting when the malady is increasing, if physical exertion is the exciting cause there is a remarkable constancy in the degree of such which induces an attack, so that the patient comes to know from experience what kind or rate or amount of effort which will probably, if not almost always, bring on an attack; and this also applies in considerable, though less, degree as regards the other exciting causes. Another is the relative absence of variation in the locality and radiation, the character, and the severity of the pain. These are of considerable diagnostic value. The infrequency of the increase in the respiratory rate is of some diagnostic significance; and if such is pronounced, it may be assumed that there is definite involvement of the myocardium. If the patient is seen during an attack his attitude and expression are of help. Lastly, in the vast majority of cases, at least in the earlier stages, the symptoms are immediately relieved by nitrites.

The results of clinical and instrumental examinations, those indicative of atheroma of the coronary arteries, atheroma of the aorta, and fibrosis of the myocardium, are the most important. For clinical electro-cardiography, see p. 1022.

Angina pectoris should be distinguished from indigestion; coronary occlusion; pain in the præcordium of extrinsic origin; the pain of cardiac failure; biliary, intestinal and renal colic, especially the first; acute pleurisy and acute pericarditis; pleurodynia and intercostal neuritis; arthritis of the dorsal spine or of the left shoulder joint; and intrathoracic aneurysm and new growth.

Angina pectoris, especially the less severe attacks, is very frequently mistaken for indigestion. There are three main reasons for this: (1) Patients suffering from angina are more likely to get an attack during physical exertion after a meal, and therefore not infrequently regard the attack as of gastric origin. (2) In angina pectoris, the locality of the pain is often in the lower part of the front chest, or epigastrium, or both. (3) As the attack subsides, the patient may belch up a large quantity of wind, with subsequent relief. In the differential diagnosis, *whenever an individual in middle or later life, especially a male, complains of pain in the epigastrium or lower part of the front of the chest after meals, inquiry should invariably be made whether such occurs only, or especially, on exertion after meals: and, moreover, whether he is subject to pain on exertion irrespective of meals.* In indigestion usually the pain does not reach so high, and there is an absence of radiation in certain directions. The response to nitrites and suitable remedies for indigestion respectively is of diagnostic value. The distinguishing features between angina and coronary occlusion are described on p. 992. Pain of extrinsic origin and that indicative of cardiac failure are described on p. 877, and should present no difficulty. Among other things, in angina pectoris the pain in the great majority of cases is situated either in the retrosternal region or across

the front chest; when physical exertion is the cause, the attacks almost always occur *during* it; and they are of shorter duration.

The diagnosis between severe angina pectoris and biliary colic in which the pain is situated in the epigastrium or lower retrosternal region may be difficult, especially as the pain of the latter may radiate upwards anteriorly, possibly as high as the neck; and, moreover, it should be remembered that the two maladies may co-exist. A careful consideration of the respective features will, however, almost always result in a correct diagnosis. Thus, in biliary colic there is an absence of an exciting cause; the onset and termination are still more sudden; the pain radiates also in other directions characteristic of that malady; it never involves the arms; there is great restlessness, and there is usually nausea and vomiting.

Prognosis.—This is less difficult than formerly, for it is now more possible to determine the nature and severity of any associated cardio-vascular morbid condition. Nevertheless, it is still very difficult, for the malady is exceedingly varied and one of its characteristic features is the uncertainty of its outlook. Death may occur even during one of the first few attacks; it may take place during what appears to be a mild attack; and the attacks may cease for years, and even after the severest attacks there may be no recurrence. Taking cases as a whole, the average duration of life after the first attack is certainly less than ten years. A few, however, live to old age.

In any given case, the following points require consideration: the ætiology; the nature and severity of any associated cardio-vascular organic disease; how easily the attacks are induced—for example, in the case of physical exertion whether on the one hand only on hurrying up an incline or on the other even when walking slowly on the level; the severity of the attacks, how long they persist after the cessation of the exciting cause, and their frequency; are they becoming more easily induced, or more severe, or more frequent; the nature of the exciting cause; do the attacks occur while at rest; whether in future it will be possible for the patient to modify his manner of life so as to avoid what he has found by experience to be the exciting causes of such; and the response to treatment.

As regards the first, among the most favourable cases are those which occur in paroxysmal tachycardia, thyrotoxicosis, severe anæmia, and focal sepsis, such as in cholecystitis. Hypertension as a cause is not unfavourable, unless of very severe grade, or there is much arterial degeneration or the kidneys are involved. When chronic valvular or chronic myocardial disease is the result of antecedent acute inflammation, the outlook is much more favourable than when due to primary degenerative processes. When syphilis is the cause, the prognosis depends upon the response to treatment but is usually unfavourable. The nature and severity of any associated cardio-vascular organic disease is perhaps the most important consideration of all. This is dealt with under their respective headings. It is to be remembered that atheroma tends to be progressive. How easily the attacks are induced is probably of more significance than their severity. When emotion is the exciting cause, the outlook is better than in the case of physical exertion since it affords an opportunity for successful treatment. The latter also applies in the case of a sensitive nervous system, and this is one of the reasons why the malady is more favourable in females than in males. If attacks occur while the patient is at rest, the prognosis is usually very grave.

Treatment.—This resolves itself into two parts: A. Treatment of an attack; B. The prevention of the recurrence of the attacks.

A. Treatment of an Attack.—The patient should be warned to remain still and, as far as possible, place himself in the position he finds by experience affords him most relief, until at least several minutes have elapsed after the cessation of the attack. In the majority of cases the most efficacious and suitable remedies are the nitrites. Those most frequently used are amyl nitrite (2–5 minims or more), glyceryl trinitrate (nitroglycerine) ($\frac{1}{200}$th–$\frac{1}{60}$th gr. or more), sodium nitrite ($\frac{1}{2}$–2 grs. or more), and erythrityl tetranitrate ($\frac{1}{2}$–1 gr. or more). The last two are much more useful for prophylactic purposes. The rapidity of action of the respective drugs is in the order in which they are placed, and the duration of such inversely so. While amyl nitrite is the most rapid in its action, glyceryl trinitrate is often, if not usually, to be preferred, among other reasons being that it is less likely to cause any disagreeable effects, and is more convenient. Amyl nitrite is inhaled from a glass capsule covered with silk, which is broken. Glyceryl trinitrate is best administered in the form of tablets, which should be chewed, or placed beneath the tongue and allowed to dissolve, instead of being swallowed. Care should be taken that the preparations are fresh and can be easily used by the patient, *i.e.* that the box containing the amyl nitrite can be opened and the capsules broken easily, and that the tablets of glyceryl trinitrate are not hard. The dose of amyl nitrite or glyceryl trinitrate should be sufficient to ensure complete relief without inducing any disagreeable symptoms; and it may be necessary to repeat the dose. The effects of these remedies are sometimes enhanced by a dose of a diffusible stimulant or, if there is gastro-intestinal flatulence, of a carminative mixture. The patient should invariably carry about with him the foregoing, with instructions under what circumstances and how they should be used. If amyl nitrite and glyceryl trinitrate fail, morphine hypodermically, in sufficient dose, is indicated. Failing these, the inhalation of ether or chloroform, cautiously administered, may be tried. If the remedies enumerated are not at hand, a large dose of a diffusible stimulant (brandy, whisky, ether, or ammonia), or the application of heat over the area of the pain may be helpful. When there is collapse, suitable measures should be adopted

I would emphasise that after a severe attack of angina, the patient should have a period of rest (see also later). I have known of a number of deaths because this has been omitted.

B. The Prevention of Recurrence of the Attacks.—In the first place, the ætiology and any associated cardio-vascular affection, such as hypertension, syphilitic aortitis, focal sepsis, and severe anæmia should be reviewed. In the next place, in a certain proportion of cases the question of a preliminary rest should be considered. Such is indicated if there is tiredness or exhaustion of the heart or nervous system; or if the attacks of pain are severe and frequent, or occur when the patient is even walking slowly on the level and, still more so, while at rest; or if, in other cases, suitable treatment has proved unsuccessful. The amount of rest varies considerably. In some cases partial rest for a period suffices. In severe cases, at least some weeks and it may be months of complete rest, both physical and mental, naturally followed by a period of partial rest, is required. Thirdly, in no cardio-vascular affection other than hypertension is the patient's

manner of life of such cardinal importance. A detailed investigation of the patient's general mode of life, his occupation, habits, hours in bed, the amount and character of his sleep, how long he takes off for his meals, his mental and emotional character, and the exciting causes of the attacks, should be made.

Having done this, I would ask my readers carefully to consider the various therapeutic measures described on pages 861–875.

There is no cardiac malady in which it is more necessary for a patient to live within the limits of his strength, according to the rules laid down there. He should carefully avoid anything he has found by experience likely to induce an attack. It is advisable that he should not engage in physical exertion soon after a meal, or against a strong or cold wind. Warm underclothes, and a locality which is non-hilly and of a mild climate, are to be enjoined; while cold rooms, cold sheets at night, and hot and cold baths are contra-indicated. Flatulent distension of the stomach or colon should be attended to. Any existing obesity should, without fail, be treated.

With the object of diminishing the incidence of the attacks, sedatives are often helpful, especially if the patient suffers from an unduly excitable nervous system. See p. 863. The xanthine group of drugs are perhaps occasionally of use.

It has been suggested that treatment by insulin and dextrose may be of value in angina pectoris. There is atheroma of the coronary arteries in the great majority of cases, which must lead to impairment of myocardial nutrition. If, as seems likely, metabolic derangement in the myocardium contributes to the production of anginal pain, the application of glucose-insulin therapy should be of benefit. Five units of insulin subcutaneously, followed in fifteen minutes by 50 grammes of dextrose by the mouth, is given once daily. This may be continued for one or some weeks. Although beneficial results have been reported by a number of workers, as yet there are insufficient data to determine the value of this method of treatment and also the special indications for its use. X-ray therapy and diathermy have also been employed, and they deserve further investigation.

Glyceryl trinitrate ($\frac{1}{200}$th–$\frac{1}{100}$th gr.) may be tried as a prophylactic measure a few minutes before engaging in reasonably necessary physical exertion. When the patient is subject to nocturnal attacks, sodium nitrite or erythrityl tetranitrate at bedtime may be of help, failing which a sedative or hypnotic, including a trial of bromide, chloral and opium, is indicated.

Surgical Treatment.—During the last two decades or so, surgical treatment has been resorted to for the relief of pain; and, quite recently, with the object of establishing a collateral circulation of the myocardium and so attacking the underlying cause. The first comprises varieties of cervical and dorsal sympathectomy, paravertebral injection of alcohol, dorsal laminectomy, and removal of the thyroid gland.

Jonnesco, in 1916, introduced a variety of cervical sympathectomy, and others were tried. Later, varieties of dorsal sympathectomy were substituted. As in the case of cervical sympathectomy, dorsal sympathectomy is an open operation and general anæsthesia is usually required, but if conducted with skill the mortality is relatively low. In the great majority of cases the opera-

tion is successful in the relief of pain, but there are often some disagreeable after-effects. Paravertebral injection of alcohol is a comparatively minor procedure, does not require a general anæsthetic, and is safe. There are difficulties connected with technique but these are gradually being overcome. While not so certain in its results as dorsal sympathectomy, it is very frequently successful. Much depends upon the competence of the operator. The procedure may be repeated. A disadvantage is that a persisting severe intercostal neuralgia sometimes follows. Some cases of dorsal laminectomy, followed by relief of pain at the level of the operation but not below, have been recorded. Total removal of the thyroid gland was introduced by Blumgart and others. By diminishing the metabolic rate, the work of the heart is reduced. There is, however, some reason to believe that the relief of pain is not entirely due to this but is partly the result of damage or section of various sensory pathways, and those who hold this view prefer partial thyroidectomy, as in the case of thyrotoxicosis. Removal of the thyroid gland, total or partial, is a long operation and is more severe than is sympathectomy but in skilful hands the mortality is comparatively low and the results are good in a large proportion of cases. It is contra-indicated if there is a history of recent coronary occlusion. A period of rest in bed before and a longer one after the operation are necessary. If myxœdema follows the operation minimum doses of thyroid should be administered. Revascularisation operations in the form of pericardial implantation of subpectoral muscle and cardio-omentopexy have been performed by a number of surgeons, very notably by Beck and O'Shaughnessy. These procedures are in the experimental stage, but some brilliant results have been recorded and they certainly deserve further investigation, including experimental, and trial. There must be undoubted evidence of a deficient coronary circulation due to organic disease.

As to the question whether surgical treatment should be employed and if so which method should be chosen, the following considerations apply: An adequate knowledge of the history of the case. A thorough examination, including by radioscopy and the electro-cardiograph. An accurate diagnosis. The patient should be under observation for some time. A very careful selection of cases. At least as regards grafting operations, removal of the thyroid, and sympathectomy, very special skill and experience on the part of the surgeon is indispensable. Operative measures should be considered when pain is severe and is very easily induced, such as on walking slowly on the level, and still more so if it occurs even during rest; the malady is increasing in severity; various other methods of treatment, including at least several months complete rest, have been tried and failed; and particularly if the condition of the heart itself is relatively little affected. If the disadvantage of troublesome intercostal neuralgia sometimes following the procedure could be overcome, paravertebral injection of alcohol might well be tried more frequently. The grafting operations appear to be the most likely of all to have permanent results. Formerly it was considered that when there is organic disease of the heart, the coronary arteries, or the aorta, the pain is a protective measure and its removal may be fraught with danger. Less is now thought of this. Even so, it is highly important that the patient should live within his cardiac strength. Lastly, it is probable that the attitude as a whole in this country towards the surgical treatment of angina is too conservative.

CORONARY OCCLUSION WITH INFARCTION OF THE HEART

Synonym.—Coronary Thrombosis.

Ætiology and Pathology.—Coronary occlusion with infarction of the heart occurs most frequently in those who are passing from middle to elderly life, and is much more common in males than in females. Not infrequently there is a history of hypertension. It has been pointed out that complete occlusion of a coronary artery is almost always due to atheroma, usually occurring suddenly as the result of thrombosis but sometimes gradually due to a progressive narrowing of the lumen of the vessel caused by the disease-process itself; and is also rarely the result of embolism, in which event the occlusion is sudden. See p. 948. The general consensus of opinion is that in about half the cases there is a previous history of angina pectoris. In my opinion, if a full and accurate history were obtained in all cases, the percentage would be materially higher.

The descending branch of the left coronary artery near its orifice is most commonly affected, with infarction of the wall of the left ventricle near the apex, especially the anterior portion, and the adjacent part of the inter-ventricular septum; and the next most frequent is either the right coronary artery or the circumflex branch of the left, with infarction of the posterior wall of the left ventricle near the base. A mural thrombus on the inner surface of the infarct is of frequent occurrence. This may give rise to embolism in the brain, kidneys, spleen, intestines, limbs or elsewhere. If the infarct extends to the pericardium, fibrinous pericarditis results. Connective tissue proliferation takes place around the necrosed tissue. Sometimes the infarction undergoes autolytic softening, a condition which is called myomalacia cordis. Rupture of the heart at the site of the infarct may take place at once, with resultant hæmo-pericardium; or an aneurysm may develop, which later on may rupture; or there may merely be a fibrous scar.

Symptoms.—The most common and prominent symptoms at the onset are pain, shock and circulatory collapse, dyspnœa, and perhaps nausea and vomiting, the first being the most frequent.

The pain is independent of any exciting cause excepting possibly fatigue, and may occur during sleep. Its onset is usually sudden. The locality and distribution are the same as in angina pectoris (see p. 984) except that probably the former is relatively more frequent in the epigastrium and there is less tendency to radiation. The pain is usually severe and may even amount to anguish, but it may be moderate or even slight. It generally persists, it may be for hours or even days—status anginosus. Angor animi is more frequent than in angina. Unlike angina, the patient is usually restless and may not be able to refrain from moving about, and the pain is not relieved by vaso-dilators or by rest. The pain is often accompanied by a sensation of oppression or constriction. Occasionally there is oppression or constriction without pain.

When there is shock and circulatory collapse, there is pallor, it may be tinged with cyanosis, the expression is anxious, the skin is cold and moist, and there may be profuse sweating. The mind is generally clear. The blood pressure almost invariably falls, usually immediately, and generally con-

siderably and it may be even markedly, and in some cases it continues to fall for some days. The diastolic is relatively less affected. The pulse is of smaller amplitude and weak and may be imperceptible. It is usually increased in frequency, it may be to 110–120 or more, but occasionally is not so and rarely there is bradycardia. The cardiac sounds, especially the first at the apex, and the force of the apex-beat are generally diminished.

Dyspnœa is present in the majority of cases, and is usually severe. When there is nausea and vomiting, it is usually at the onset but it may be later. The bowels may be moved, and very occasionally there is diarrhœa. Flatulence and distension of the abdomen are frequent. There may be acute left, or, less frequently, right ventricular failure.

Slight or moderate pyrexia is usual during the first few hours. There is often a moderate leucocytosis, the polynuclears being relatively increased in number. Localised pericardial friction in the area of the infarct is not infrequent, and is of great diagnostic importance. It generally occurs a few days after the onset, and may be transient but may persist for a few days. Embolism (see p. 991) may occur.

There is frequently some disorder of rhythm: extrasystoles, or, less frequently, paroxysmal or persistent auricular fibrillation or auricular flutter, paroxysmal tachycardia, or auriculo-ventricular block.

The foregoing is a description of the clinical features of a typical case. It is to be noted, however, that the clinical picture varies considerably in different cases. Thus: Pain (or a sensation of oppression or constriction) may be only slight and rarely completely absent. Shock and circulatory collapse, or acute left or right ventricular failure may be the most prominent and even the only symptoms. The clinical picture may resemble that of an acute abdominal condition, especially if embolism in the abdomen has occurred. Lastly, occasionally the symptoms develop insidiously.

For the results of electro-cardiographic examination, see pp. 1023–1027.

Diagnosis.—A correct diagnosis is almost always possible from the clinical features described, together with the results of electro-cardiographic examination; indeed, in the great majority of cases, it may be made from a careful consideration of the first alone. The diagnostic value of the electro-cardiograms is discussed on pp. 1023–1027.

Coronary occlusion should be differentiated from angina pectoris, acute left- or right-sided ventricular failure due to other causes, rupture of an aneurysm of the thoracic aorta, acute pericarditis, pulmonary embolism, lobar pneumonia, pneumothorax, and acute abdominal conditions, such as the perforation of a peptic or duodenal ulcer, biliary colic, and acute pancreatitis.

The distinguishing clinical features between coronary occlusion and angina pectoris are that in the former the pain is not related to any exciting cause, it generally persists and it may be for hours or even days, is usually accompanied by restlessness, and is not relieved by vasodilators or by rest; there is often shock and circulatory collapse; dyspnœa is generally present and is usually severe; there is frequently nausea and vomiting; there may be acute left- or right-sided failure; there is often some form of arrhythmia present; there is generally pyrexia and often leucocytosis; pericardial friction is not uncommon; and embolism may occur. Coronary occlusion and acute abdominal conditions are more likely to be confused when in the former the locality of the pain is in the lower part of the front

chest or in the epigastrium, and especially if there is nausea and vomiting; and when in the latter the pain involves the lower part of the front chest. Among the distinguishing features are the following: In acute abdominal conditions the pain is *chiefly* abdominal, does not spread so high in the chest, and never involves the arms; pallor is not tinged with cyanosis; there is not such an immediate considerable fall in the blood pressure; and severe dyspnœa, or acute left- or right-sided failure, does not occur. The age and sex, the previous history, *i.e.* whether pointing to a cardiac or an abdominal complaint, and the results of the examination of the heart and of the abdomen —in which connection it may be mentioned that if in coronary occlusion there should be muscular rigidity in the abdomen it is never pronounced. Lastly, in the differential diagnosis of coronary occlusion from any other malady, the results of electro-cardiographic examination are usually of great value.

Prognosis.—This exhibits a wide variation. It is less unfavourable than was considered some years ago, one of the reasons for this being that milder cases are now more frequently diagnosed. Taking cases as a whole, it would appear that somewhat more than half survive the attack. The first three weeks is particularly dangerous, and the prognosis must be very guarded.

In trying to form an opinion, the severity and duration of any existing pain, shock and circulatory collapse, dyspnœa, pyrexia, leucocytosis, the variety of any disorder of rhythm, whether there is acute left- or right-sided failure, the size of the heart, the degree and duration of any electro-cardiographic changes, and the question of complications should be taken into account. Treatment also is very important. As to the subsequent outlook, published statistics suggest that of those who survive about half live for two to three years, about a quarter for five years, relatively few for over ten years, and very rarely for more than fifteen years. In the vast majority of cases the reserve strength of the heart is diminished, in varying degree. A small proportion can lead a fairly active life. Angina pectoris occasionally supervenes. On the other hand, if the patient was previously subject to this malady, it may become less. Recurrence of occlusion is not infrequent. In conclusion, I wish to state that in my opinion, based on a considerable experience, if (1) as regards the attack there is a sufficiency of rest (see *infra* and p. 994), and (2) afterwards the patient is able and willing to live within the diminished strength of his heart, however limited a life may be involved (see pp. 862, 863), the prognosis in coronary occlusion would be very materially bettered than would otherwise be the case and the statistics suggest.

Treatment.—In 1933 I expressed the firm opinion that whenever a definite diagnosis of coronary occlusion has been made, at least three months complete rest, physical and mental, followed by a similar period of partial rest, is strongly indicated; and that in severe cases the duration should be longer. Further experience has confirmed this view. It is of the utmost importance to afford a full opportunity for the best possible healing of the infarct.

In the early stages the more absolute the rest and tranquillity of mind the better. For this purpose, adequate nursing, night and day, is essential. Great care should be taken regarding movement of the bowels; death may take place during the act of defæcation. They need not be moved for the

first 48 hours, and for some time afterwards every other day is usually sufficient. They should be opened by means of enemata. Warmth to the body is indicated. For the control of pain, morphine hypodermically, in sufficient dose and frequency, and for as long as is found to be necessary. Nitrites are contra-indicated. Later, milder sedatives may be very helpful to ensure a sufficient amount of sleep and for restlessness. Especially during the first one or two weeks or even longer, the diet should be fluid or semi-solid, easily digestible, limited in amount, and given in small quantities at a time and at frequent intervals. It is increasingly believed that a low calorie diet, with the object of diminishing the metabolic rate, is of notable assistance. If congestive cardiac failure occurs, digitalis should be administered but large doses should be avoided and caution exercised. The treatment of auricular fibrillation and of auricular flutter is dealt with elsewhere. If digitalis is employed, the precautions just mentioned should apply. Quinidine as described on p. 894 has proved successful and very valuable in some cases of paroxysmal tachycardia, especially of ventricular origin.

The greatest care should be exercised during convalescence. During the last few weeks that the patient is in bed, his back may be gradually raised by means of pillows. Afterwards, he is moved to a couch, at first only every other day, for at least four weeks. After the first two weeks of this time, massage, at first very gentle and for short periods only, and gradually increased, *may be tried*. Later, slight walking exercises may be permitted. If during any stage there are abnormal subjective symptoms, or lowering of blood pressure, or maintained increased frequency of the pulse, it means that the amount of exertion is too much and should be correspondingly reduced.

The patient should be impressed with the importance of living not only within the limits of his diminished cardiac strength (see pp. 862, 863), but even keep something in reserve, during the rest of his life.

THE HEART IN HYPERTENSION

Within recent years a good deal of attention has been paid to the heart in hypertension. The subject is of great importance.

In the vast majority of cases the hypertension is of the nature of hyperpiesia. The latter is one of the most frequent causes of heart failure. Again, in hyperpiesia, it is probable that more than half the patients die from cardiac causes.

Ætiology and Pathology.—This is mainly dealt with on pages 1065 and 1066. There is cardiac hypertrophy, especially of the left ventricle, and diffuse hyperplastic sclerosis. There may be co-existent atheroma of the coronary arteries and of the aorta, due to age, or, in the opinion of some, the result of the hypertension; fibrosis of the myocardium; dilatation of the aorta; and primary chronic degenerative endocarditis of the aortic and less frequently of the mitral valves. The fibrosis of the myocardium may be of ischæmic origin; or due to the same cause as that of the hypertension; or to the increased resistance to the work of the heart having an effect upon its nutrition and removal of waste products; or to a combination of some of these.

In the course of time dilatation follows hypertrophy, and at necropsy it is usual to find both present.

Symptoms.—The symptoms of hyperpiesia are described on page 1066. The most common cardiac symptoms are shortness of breath, palpitation, and precordial discomfort or pain, on exertion. Later, cardiac failure, usually left-sided, but it may be involving both sides, may supervene (see p. 857). Acute left-sided failure may occur (see p. 853). Angina pectoris is not very infrequent. There is occasionally coronary occlusion.

There are physical signs of hypertrophy of the heart, especially of the left ventricle (see p. 955), and in the course of time of dilatation (see p. 956). There may be a systolic murmur in the aortic area, the result of dilatation or of atheroma. In the case of the first, the second sound is accentuated and may be ringing. There is sometimes mitral incompetence and rarely aortic incompetence, in both usually relative, but it may be the result of primary chronic degenerative endocarditis. X-ray examination reveals hypertrophy of the left ventricle, and there may be, in addition, general dilatation of the aorta (see Fig. 45). The latter is shown by general widening of the supra-cardiac

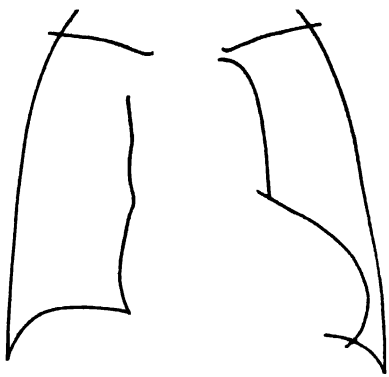

Fig. 45.—Orthodiagram from a case of hypertension, showing great enlargement of the left ventricle, and general widening of the aortic shadow.

vascular shadow. There may be also increased density of the shadow. The rhythm of the heart is usually regular, but extrasystoles are not infrequent, while occasionally there is paroxysmal tachycardia, or auricular fibrillation, or auricular flutter—in that order of frequency. There may be one of the varieties of auriculo-ventricular block, bundle-branch block, or arborization block. The electrocardiogram almost always indicates preponderance of the left ventricle. It is frequently inverted.

During the last few days or weeks the blood pressure may fall, especially the systolic, with a resultant diminution in the pulse-pressure.

Diagnosis.—The diagnosis is easy in the absence of any material fall of the raised blood pressure. When the blood pressure has diminished with the onset of heart failure, or on account of the associated coronary disease, it may present difficulty. In these cases a relatively high diastolic pressure is significant. Gross hypertrophy of the heart in the absence of chronic valvular disease is generally due to hypertension. The results of X-ray examination of the heart and aorta provide valuable evidence. In this con-

nection it is necessary to distinguish between general dilatation of the aorta due to hypertension from that caused by syphilitic mesaortitis. The changes of the aortic shadow in the latter condition are described on page 977. Moreover, in atheroma, on account of lengthening with tortuosity of the aorta, localised bulging of any part of the shadow is far less common. Gallop rhythm and pulsus alternans are valuable signs. Ophthalmological examination may show characteristic changes.

Prognosis.—This depends upon the blood pressure readings, especially the diastolic, the size of the heart, the condition of the myocardium, of the aorta, the coronary arteries, and of the kidneys, and the degree of any existing cardiac failure. If the state of the myocardium, the aorta, the coronary arteries and the kidneys is good, it is surprising how long the heart is able to support a raised blood pressure. Gallop rhythm and pulsus alternans are of serious significance; and cardiac asthma and acute pulmonary œdema are usually of grave import.

Treatment.—The treatment of hyperpiesia is dealt with on pages 1068–1070. When congestive cardiac failure occurs, complete rest in bed for a time, its duration depending upon the degree of the failure, and digitalis are indicated. Venesection may be helpful when there are indications of great distension of the right side of the heart. The various other therapeutic measures, including the question of diuretics, described on pages 861–875 should be carefully considered.

HYPERTHYROIDISM IN RELATION TO HEART DISEASE

The effects of hyperthyroidism, due either to Graves's Disease or to secondary thyrotoxicosis (toxic adenoma), on the heart and circulation have been discussed under their respective headings. It is, however, appropriate to make some observations on one of the varieties of "masked" hyperthyroidism (see p. 488), namely, that in which the cardio-vascular symptoms dominate the clinical picture or may even entirely mask any other manifestations.

Clinical Features.—The condition occurs most commonly in middle-aged or elderly subjects, and females are much more often affected than males. It is relatively more frequent in secondary thyrotoxicosis.

The onset of symptoms is usually gradual. The patient seeks medical advice for cardiac symptoms. Palpitation is the most frequent; it is without apparent cause. There is tachycardia, and an abnormal response of the cardiac rate to physical exertion and emotion. The tachycardia is little affected during sleep; and persists in spite of rest. The pulse is fuller and of increased force, and may resemble that of aortic incompetence. There is exaggerated pulsation of the arteries, which may be particularly noted in the carotid and trachial arteries. There may be capillary pulsation. The systolic blood pressure is generally moderately increased; the diastolic may be subnormal, normal, or slightly raised; the pulse pressure is increased. In some cases the systolic and diastolic pressures are proportionately raised. In the opinion of some this is not always due to a co-existing condition, but may be the result of the thyrotoxicosis. There may be extra-systoles; in which connection, the association of extra-systoles with tachycardia, in the absence

of other causes, is very suspicious of hyperthyroidism. There may be auricular fibrillation, at first usually paroxysmal, and later it may be persistent. Paroxysmal tachycardia and auricular flutter are of relatively rare occurrence. The apex-beat is more forcible than normal, but the out-thrust is quicker and shorter—unlike in hypertrophy, in which it is slower and longer than normal. It is often diffuse. There may be a sensation communicated to the hand resembling a systolic thrill. The first sound is increased in loudness, and not infrequently is short and sharp. There may be a systolic murmur in the pulmonary area, or at the apex, especially the former, in which event the murmur is usually harsh and may give the impression of being superficial, and cases have been recorded in which a slight thrill was present. X-ray examination of the heart is of considerable help in diagnosis. It almost always shows overaction of the organ, as revealed by increased pulsation. Even in the early stages, the left contour of the cardiac shadow is straight, due to increased prominence of the pulmonary arc. This may be diagnosed from mitral stenosis by examining the patient in the right oblique position, when absence of enlargement of the left auricle is to be noted. The size of the heart is less than would be supposed from clinical examination. In cases of considerable severity and duration, however, there is enlargement to both sides, often mainly to the left. When enlargement is very considerable, there may be relative mitral incompetence.

Breathlessness is less pronounced than palpitation, unless there is cardiac failure. Angina pectoris is occasionally met with, especially in the elderly, in which there is more likely to be coronary disease. Ultimately congestive cardiac failure occurs in the great majority of cases, in which event there is usually auricular fibrillation. The most common complications are auricular fibrillation and congestive failure.

There is nothing characteristic about the electro-cardiograms.

The skin may be warm and moist, and there may be flushing and excessive sweating. In some cases there is slight pigmentation of the skin. There may be slight enlargement or increased consistency of the thyroid gland. Occasionally there is a substernal or rarely an intrathoracic goitre. Exophthalmos is rare, but there may be a slightly staring expression. Fine tremors are present in most cases. Usually there is loss of weight, but generally not rapid and only occasionally severe.

The estimation of the basal metabolism is a valuable aid in diagnosis. It should be done under suitable conditions, and in doubtful cases on a number of occasions. The rate is almost invariably increased. In this type of case a great augmentation is ralatively rare, the increase usually being between plus 30 and 50. And even if the rate is within the normal limit of plus 15, if the administration of iodine is followed by a pronounced effect on the rate and the clinical picture is suspicious, in all probability there is hyperthyroidism. It should be noted that congestive failure may give rise to a slight or moderate increase in the basal metabolic rate.

Diagnosis.—Formerly a large proportion of these cases were missed and even now such is not infrequent. Whenever a patient, especially if middle-aged or elderly, complains of cardiac symptoms, in the absence of other causes, such as rheumatism, hypertension, and syphilis, the possibility of a thyroid origin should always be borne in mind. In this regard, a careful consideration of the various features just described is indicated. Evidence of overaction of

the heart, together with a straight left contour of the shadow is exceedingly suggestive.

In addition, the effect of digitalis, quinidine, and iodine therapy respectively should be taken into account. There may be little response to digitalis, even when auricular fibrillation (or auricular flutter) with a rapid ventricular rate is present. Although quinidine not infrequently restores the normal rhythm, if the thyrotoxic state persists, relapse almost invariably recurs. The question of iodine has been referred to.

In possible early cases, neurocirculatory asthenia should be excluded.

Prognosis.—The degree of damage to the heart in hyperthyroidism seems to depend on the age of the subject and its duration rather than on the type of goitre or the severity of the symptoms of hyperthyroidism. It is more serious with advancing age. The prognosis in this group of cases depends almost entirely on treatment. Provided partial thyroidectomy is performed before the cardiac condition is hopeless, improvement is almost invariable. Those with congestive failure respond very well. In cases of auricular fibrillation, the abnormal rhythm sometimes ceases spontaneously after operation, although such may be delayed to even three to six months. If this does not occur, the administration of quinidine is usually successful. Any co-existing hypertension usually persists after operation.

Treatment.—The primary indication is to remove the thyrotoxic condition. This has already been dealt with on pp. 488–491. As far as my experience goes taking a long view, in the vast majority of this group of cases partial thyroidectomy is the best form of treatment. And, given time for preliminary treatment, it should not be postponed. Severe congestive failure, even requiring mercurial diuretics, is not a contraindication. Needless to say, however, I am not referring to moribund cases.

The opinion I have expressed does not diminish the importance of medical treatment, both before and after operation. With regard to the former, the indication is to get the patient to the optimum. Measures include rest, diet, sedatives, iodine, and perhaps digitalis and the removal of foci of infection. These have been dealt with elsewhere. It is a good thing to commence the various forms of treatment at various times, so as to secure the maximum beneficial result simultaneously. If after operation auricular fibrillation or auricular flutter does not cease spontaneously, provided there are no contraindications, the administration of quinidine should be resorted to.

THE HEART IN HYPOTHYROIDISM

The heart is affected in some manner in the vast majority of cases of hypothyroidism, whether myxœdema, either natural or following thyroidectomy, or cretinism.

In such cases there is often some degree of cardiac failure. Slight degrees, such as some shortness of breath on exertion and slight œdema, are the rule; and severe failure is probably of rare occurrence unless there is co-existing chronic myocardial disease or hypertension. The heart is sometimes enlarged, both sides being implicated. The degree of the enlargement is usually not great, but it may be very great or even enormous. The cause of the enlargement is uncertain. In the opinion of some it is mainly due to dilatation and to

a less extent to a myxœdematous state of the heart muscle. The degree of cardiac failure is not always related to that of enlargement. The rate of the circulation is diminished. On screening, in addition to possible enlargement of the heart, there is diminished pulsation. Changes in the electro-cardiogram are the most constant features (see p. 1029).

There may be indications of co-existing chronic myocardial disease, atheroma or hypertension.

A diagnosis may be made from the general symptoms of hypothyroidism, together with the clinical features described and an electro-cardiogram; and the response to appropriate treatment.

Treatment consists of thyroid therapy, given cautiously. The beneficial effect is very quick, including the cardiac enlargement and the electro-cardiogram.

FREDERICK W. PRICE.

CLINICAL ELECTRO-CARDIOGRAPHY

By means of the electro-cardiograph it is possible to obtain graphic records of the movements of both auricles and ventricles, to study the time-relations of their contractions, and to measure the function of conductivity not only of the auriculo-ventricular junctional tissues but also that below the division of the auriculo-ventricular bundle into two branches. In addition. it tells us the point of origin of the impulse formation and also the path along which the wave of excitation travels.

All the various forms of irregular action of the heart can be identified with certainty. The electro-cardiograph affords the most precise means of investigating the function of the myocardium. Disease of the myocardium may, by interfering with the normal path of the wave of excitation, modify the form of the ventricular complex. The instrument is often of great value in the diagnosis of coronary disease and infarction of the heart; it contributes the most certain sign of transposition of the heart; it gives evidence of left- or right-sided preponderance when either exists; it is sometimes of value in the diagnosis of chronic valvular disease and congenital morbus cordis; and during the administration of quinidine in the treatment of persistent auricular fibrillation and persistent auricular flutter, the changes in the cardiac rhythm induced by the drug may be followed, and the dosage controlled accordingly.

It has been known for a considerable time that changes in electric potential take place in muscle when it contracts, and, further, that a record of these changes may be obtained by connecting the muscle with a sensitive galvanometer by means of electrodes.

A. D. Waller, in 1887, employed a capillary electrometer to register the changes in electric potential in the human heart during contraction. He demonstrated that these changes were distributed through the body, and he used the moist skin surfaces of the arms and legs as leads, connecting them with a galvanometer.

Einthoven employed the string galvanometer to register the changes

in electric potential in the human heart. He modified this instrument, the Einthoven string galvanometer being now generally employed in physiological and clinical investigations. In the Einthoven galvanometer there is an exceedingly fine silvered glass fibre, which is suspended in a box and placed vertically between the poles of a powerful electro-magnet. When a current passes through this fibre, minute movements of the fibre take place. The shadow of the oscillating fibre is magnified, and projected on to a photographic screen, and in this way a photograph of these movements is obtained. The sensitiveness of the fibre can be adjusted by altering the tension, the standard generally adopted being that of Einthoven, *i.e.* that when a difference of potential of one millivolt is passed through the fibre, this gives a deflection on the plate of 1 cm. in amplitude.

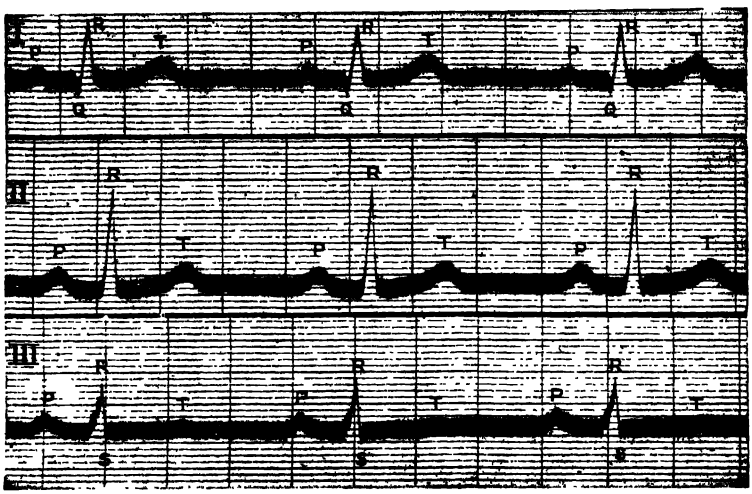

FIG. 46.—A normal electro-cardiogram of leads I, II, and III. The first deflection, *P*, is due to the contraction of the auricles: the others are the result of the contraction of the ventricles, and are termed *Q*, *R*, *S*, and *T*. In normal subjects the amplitude of all the deflections is usually greatest in lead II, especially the deflection *R*.

Recently some workers employ valve modification and a mirror galvanometer instead of the string galvanometer.

Both varieties of electro-cardiographs are now made in reliable portable form, which can be taken to the bedside of the patient.

Formerly the common practice was to accept three leads and the following nomenclature, *i.e.* lead I, or the transverse, a lead from the right and left hands; lead II, or the axial, from the right hand and left foot; and lead III, or the left lateral, from the left hand and left foot. Now a fourth or chest lead is also employed, in which one electrode is applied over the præcordium and another over some distant part of the body. This lead, on the joint recommendations of the Cardiac Society of Great Britain and Ireland and the American Heart Association, is arranged as follows: One electrode is placed over the extreme left border of the apex-beat, or, if this

cannot be determined by palpation, it may be applied in the fifth intercostal space immediately outside the left border of percussion dulness, or just outside the left mid-clavicular line. The other electrode is applied either to the left leg or to the right arm. The leads so arranged are referred to as leads IV *F* and IV *R* respectively. In using either of the foregoing connections, the correct polarity is obtained as follows: The lead switch is turned to lead I; the left arm terminal is connected to the præcordial electrode; and the right arm terminal is connected to the distant electrode—to the left leg for lead IV *F*, or to the right arm for lead IV *R*.

The record of the changes in electric potential which take place in the heart during contraction is called an electro-cardiogram.

If a normal electro-cardiogram of leads I, II, and III be studied, certain

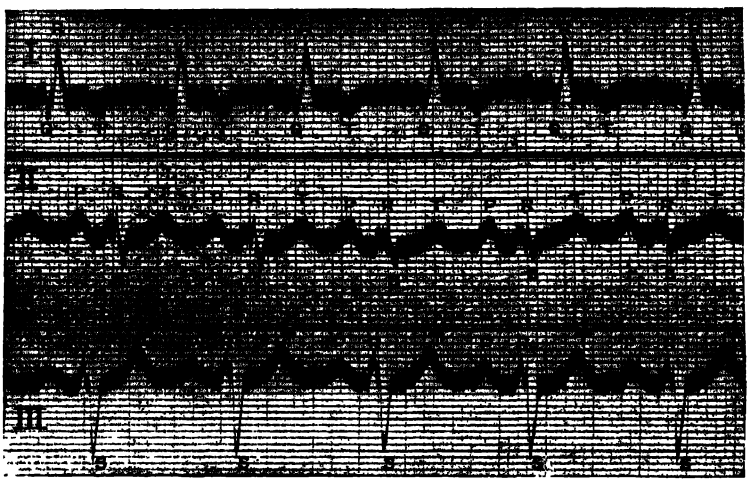

FIG. 47.—Electro-cardiogram, showing inversion of *T* in lead I. There is also left-sided preponderance.

upward and downward deflections or waves are seen in each cardiac cycle (Fig. 46). Following Einthoven, the deflections are called *P*, *Q*, *R*, *S*, and *T*, in some instances *T* being followed by *U*. *R* and *T* are the most constant deflections, the former especially so; *Q* and *S* are not infrequently absent, particularly the first; while the *U* deflection is of very uncommon occurrence.

P, *R*, *T*, and *U* are upward deflections, while *Q* and *S* are downward ones.

The *P* deflection is due to the contraction of the auricles. *Q*, *R*, *S*, and *T* are due to the contraction of the ventricles. *U*, if present, occurs early in diastole, and its significance is not fully understood.

That portion of the elcctro-cardiogram from the beginning of *P* to the commencement of *Q* is called the auricular complex. *P* represents the spread of the wave of excitation over the auricles. It is an upward, small, and usually rounded deflection, but it may be pointed. It is succeeded by an

isoelectric interval indicated by the string either remaining at the zero level, or descending or ascending slightly, in which event usually the former.

That portion of the electro-cardiogram from the beginning of *Q* to the end of *T* is designated the ventricular complex. *Q*, *R*, *S* constitute the initial group of deflections, while *T* is the terminal or final deflection. *Q* passes at once into *R*, and *S* follows immediately upon the latter. *Q* and *S* are downward steep deflections, and usually very small. *R* is an upward, conspicuous, sharp spike, and of greater amplitude than any of the other deflections. The *S–T* interval usually exhibits a pronounced zero-line, which however may descend or ascend slightly, but, on the other hand, there may even be no zero-line. *T* is an upward, prominent, broad and rounded deflection, but in lead III it not infrequently points downward (see p. 1004).

In normal subjects, the amplitude of all the deflections, especially *R*, is

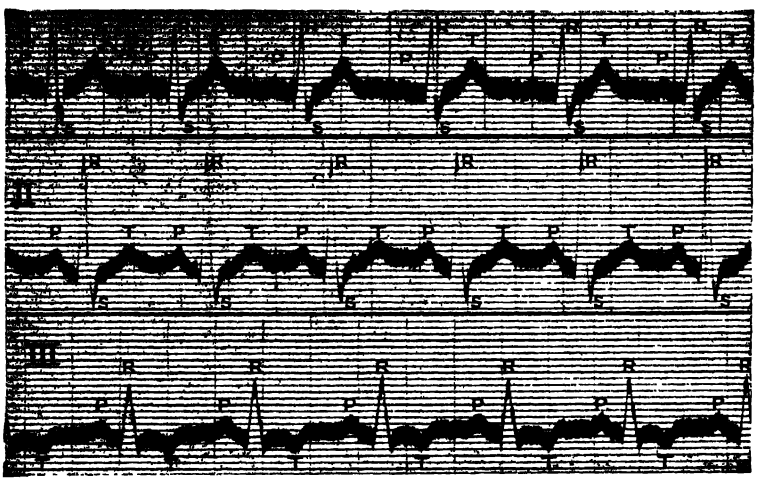

FIG. 48.—Electro-cardiogram showing inversion of *T* in lead III.

usually greatest in lead II, while those in lead III are not infrequently of small amplitude.

The time-distance between the beginning of *P* and the commencement of *Q*, or between *P* and *R*, as the case may be, is an index of the *As–Vs* interval, that is, the interval separating the commencement of auricular and ventricular contraction, and is a measure of the function of conductivity of the auriculo-ventricular node and bundle above its division into two branches; it is called the *P–Q* or *P–R* interval. The rule is to employ the latter, on account of the frequent absence of the *Q* deflection. The *P–R* interval is a more reliable indication of the rate of conduction of the wave of excitation than the *a–c* interval in a polygraphic tracing, because the presphygmic interval and the period between the opening of the aortic valves and the carotid pulse are not included. In normally acting hearts the interval varies between 0·12 and 0·18 second. If it exceeds the latter, and certainly if more than 0·20 sec. (Fig. 78), we may conclude that the

function of conductivity is definitely depressed. The *P-R* interval is diminished in auriculo-ventricular nodal rhythm and in functional bundle-branch block (see Fig. 82).

The period of time occupied by the ventricular complex is approximately that of the ventricular systole. That occupied by the *QRS* group of deflections is of much importance. It should not exceed one-tenth second. If it does it indicates a delay in the conduction of the wave of excitation through the ventricular muscle. This occurs in bundle-branch block, arborization block, ventricular extrasystoles, in the ventricular variety of paroxysmal tachycardia, and, it may be, in extreme preponderance of either ventricle.

The *Q–T* or *R–T* duration varies considerably. With a normal cardiac rate, it probably averages between 0·32 to 0·35 second. It is diminished by an increased cardiac rate, and *vice versa*. When the cardiac rate is unusually frequent the duration of the diastolic interval is so shortened that the deflection *T* approaches more and more to the following *P*, and *P* and *T* may even coincide and are superimposed (Fig. 49).

In auricular hypertrophy, such as in mitral stenosis and congenital

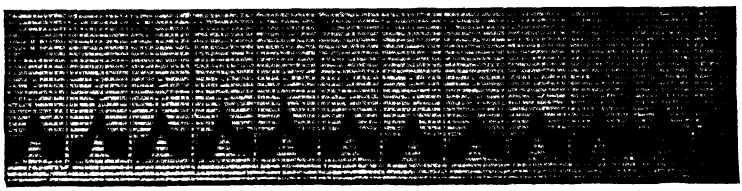

FIG. 49.—Electro-cardiogram in which *P* and *T* coincide and are superimposed.

pulmonary stenosis, especially the former, the *P* deflection, particularly in lead II, is of increased amplitude (Figs. 53 and 54), and not infrequently is also broad and has a flat top, and may be notched or bifurcate (Figs. 55 and 56). Some writers are of opinion that a mere increase in the amplitude of *P* is occasionally met with in normal hearts.

A large *Q* in lead III is often a feature of the *T*3 type of infarction, either recent or old. It should be noted, however, that it may also occur with a horizontal or transverse position of the heart due to a high diaphragm, as, for example, in ascites, pregnancy, or obesity. In the differential diagnosis, whether there is also a *Q* of somewhat smaller amplitude in lead II and a characteristic alteration in the *R–T* (*S–T*) interval and in the form of the *T* deflections are of cardinal importance. In addition, a large *Q* due to upper displacement of the diaphragm is diminished or abolished by holding the breath after a deep inspiration. A *Q* in lead I is strongly suggestive of an old infarct of the wall of the left ventricle near the apex and the adjacent part of the interventricular septum.

Notching or splintering or slurring of the *QRS* complex of slight degree may be found in normal conditions, and in preponderance of either ventricle. These in pronounced degree and also notching which is irregular signify that the wave of excitation is speading in the different parts of the ventricular musculature in an abnormal manner. They may be met with in bundle-

branch block, arborization block, ventricular extra-systoles, and in the ventricular variety of paroxysmal tachycardia.

Diminution in the amplitude of *T* occurs during forced expiration, and it may be with advancing age. The *T* deflections may be flattened or inverted in the three leads in hypothyroidism (see Fig. 95). Diminution of *T* in lead II is frequently met with in marked left- or right-sided preponderance. Inversion of *T* in lead III alone (Fig. 48) is not infrequently found in health, and therefore its significance in a single examination is uncertain and it is of essential importance to know whether the deflection was formerly upright. Among pathological conditions, it is found in marked right-sided preponderance. Inversion of *T* in lead III and lead II may occur during forced expiration. Apart from this, it is probably pathological.

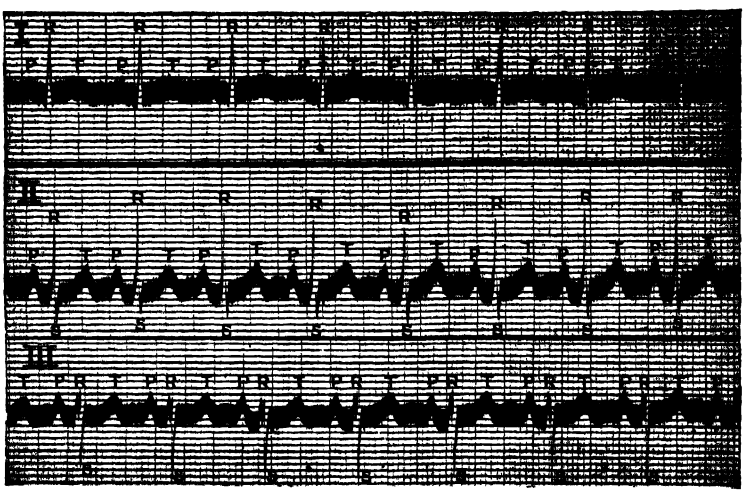

FIG. 50.—Electro-cardiogram showing predominant hypertrophy of the left ventricle.

Inversion of *T*1 and *T*2 may be regarded as pathological, suggesting coronary or myocardial disease. Inversion of *T*1 is also to be met with in gross left-sided preponderance.

The changes in the *T* deflections which occur in bundle-branch block, coronary occlusion, and with full doses of digitalis are described elsewhere.

The characteristics of a normal fourth lead are as follows (Fig. 51). The first deflection, *P*, is upright, and is rather smaller than in the other standard leads but less so in lead IV *F*. The initial group of ventricular deflections is of larger amplitude than in leads I, II, and III, and is diphasic, the first wave, *R*, being positive and the second, *S*, negative, and they are approximately of equal size. The *S–T* interval, as in the other three leads, is usually iso-electric but it may, on the other hand, show a slight inclination to rise above or to fall below the zero line. The *T* deflection is positive, and is of increased amplitude.

The form of electro-cardiographic curves depends upon the point of origin of the impulse formation, the paths along which the wave of excitation travels, and the manner of conduction of the latter; any departure from the normal in respect of one of these will result in an alteration in the form of the electro-cardiogram.

A typical *P* signifies that the impulse arises in the sino-auricular node and that the wave of excitation spreads over the whole of the auricles along the normal paths. When the auricle contracts in response to impulses not generated at the sino-auricular node, almost always the *P* deflection is of abnormal form. The degree of this depends upon the distance of the site of origin from the normal, for example, if near the node *P* may be almost normal. Often the deflection is inverted. The various forms of abnormal *P* deflections which may be found in auricular or auriculo-ventricular nodal extra-systoles, auricular or auriculo-ventricular nodal paroxysmal tachycardia, auriculo-ventricular nodal rhythm, and auricular flutter are described later. A diphasic or inverted *P* in lead III alone may occur in left-sided preponderance and in the absence of any pathological condition.

Similarly, a typical ventricular complex signifies that the contraction of

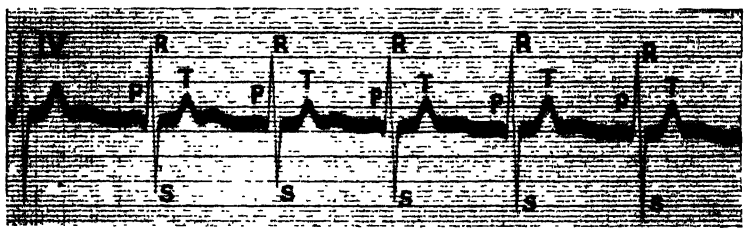

FIG. 51.—A normal electro-cardiogram of lead IV.

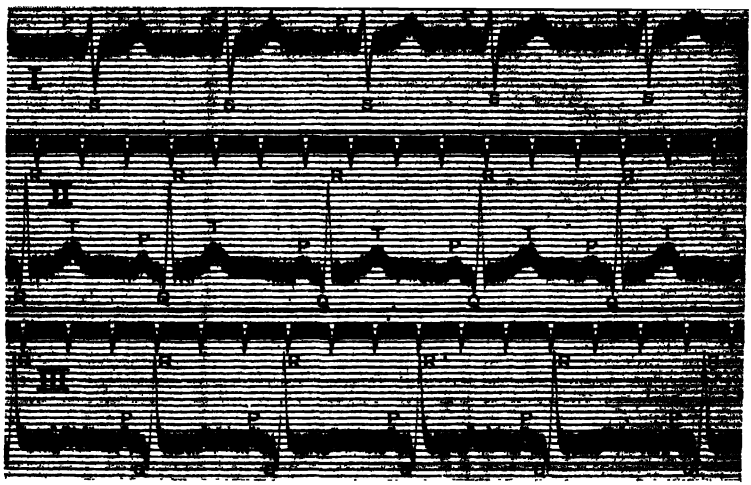
the ventricles is supra-ventricular in origin, *i.e.* they have contracted in response to an impulse which arises above the division of the auriculo-ventricular bundle, and that the wave of excitation proceeds along the normal paths. An atypical ventricular complex means that the contraction of the ventricles is ventricular in origin, *i.e.* the stimulus arises below the division of the auriculo-ventricular bundle. When the ventricular contraction is *aberrant* (see p. 847), the complex, while fundamentally typical, differs from the normal to some extent, this varying from a slight degree to even, rarely, that in which the complex resembles one of ventricular type.

CARDIAC HYPERTROPHY.—It has been previously pointed out that in cardiac hypertrophy, while both ventricles are more often affected than one alone, one ventricle is frequently involved to a greater degree than the other. This predominant hypertrophy or preponderance of either ventricle is revealed by the electro-cardiograph. If in cardiac hypertrophy an electro-cardiogram does not indicate either right- or left-sided preponderance, we may assume that the hypertrophy involves both ventricles approximately equally.

In left-sided preponderance, the amplitude of *R* is greater in lead I than in lead III, and the amplitude of *S* in lead III is greater than in lead I (Figs. 47 and 50). The deflections of greatest amplitude in leads I and III, there-

fore, point away from each other. In right-sided preponderance, the amplitude of *S* is greater in lead I than in lead III, and that of *R* in lead III is greater than in lead I (Fig. 52), and so the deflections of greatest amplitude point towards each other.



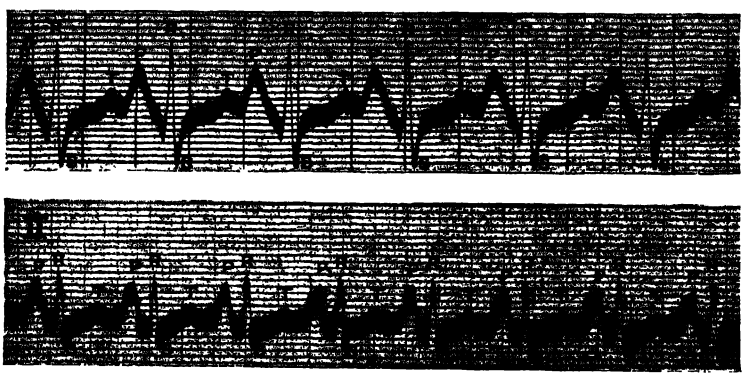


FIG. 52.—Electro-cardiogram showing predominant hypertrophy of the right ventricle.

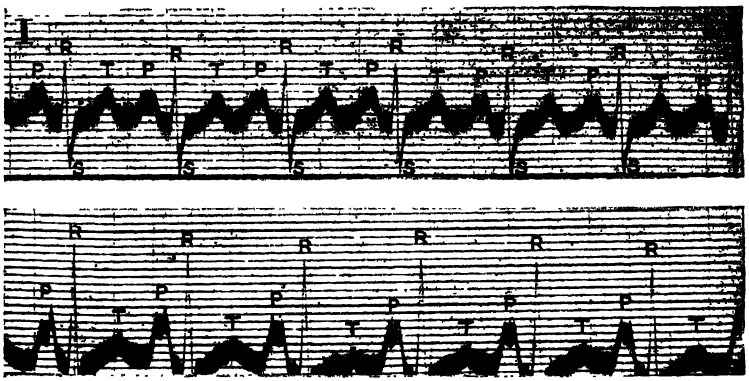
FIGS. 53 and 54.—Electro-cardiograms from two different subjects showing increased amplitude of the deflection *P*.



In marked preponderance of the left side, there is often inversion of *T* in lead I; and in that of the right side, inversion of *T* in lead III. Barnes and Whitton have suggested that these changes in the *T* deflection result from mechanical strain on one ventricle rather than actual disease of the myocardium other than hypertrophy. In extreme preponderance of either

ventricle, the period of time occupied by the *Q*, *R*, *S* group of deflections may be increased, exceeding one-tenth of a second.

In the diagnosis of preponderance of either ventricle it is necessary to exclude displacement of the heart, for the following reason. The electrical axis of the organ is influenced by the anatomical axis, so that displacement may give rise to electro-cardiographic curves of right- or left-sided preponderance. Thus, a horizontal or transverse position of the heart due to a high diaphragm tends to produce a curve of left ventricular preponderance; while a vertical position of the organ with a low diaphragm, as seen in asthenic subjects, tends to produce that of right ventricular preponderance.

It is also necessary to distinguish between predominant hypertrophy of the left or right ventricle and a lesion of the left or right main branch of the auriculo-ventricular bundle (new nomenclature) respectively. This is referred to on p. 1020.

CHRONIC VALVULAR DISEASE.—In aortic valvular disease there is usually

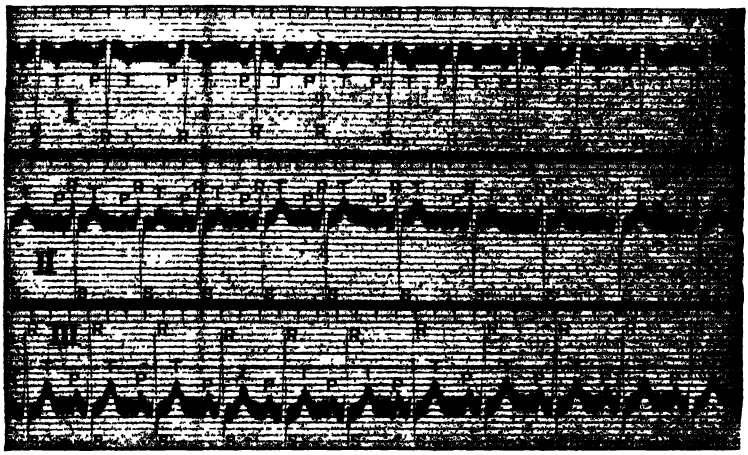
FIGS. 55 and 56.—Electro-cardiograms from two different cases of mitral stenosis. The deflection *P* is increased in amplitude, and is also broad, has a flat top, and is bifurcate.

left-sided preponderance. In mitral stenosis there is generally right-sided preponderance; and the *P* deflections may show the changes indicative of auricular hypertrophy described on p. 1003. The latter, when present, are of diagnostic value, especially when there is also right-sided preponderance. When auricular fibrillation supervenes, the curves will present features characteristic of that condition.

CONGENITAL HEART DISEASE.—The amplitude of the deflections is sometimes greater than in the acquired form of valvular disease. There is frequently right-sided preponderance, often of marked degree, especially in pulmonary stenosis.

In dextro-cardia all the deflections of a curve from lead I are inverted, while lead III is equivalent to the normal lead II, and lead II to the normal lead III (Fig. 57). This form of electro-cardiogram is pathognomonic of the condition. It is to be noted that if there is also a lesion giving rise to enlargement of the right ventricle, the electro-cardiogram will be that of left-sided preponderance with inversion of *P* in lead I. In uncomplicated wide patency of the interauricular septum there may be deviation of the electrical axis

to the right. In patency of the interventricular septum the electro-cardiogram is usually normal, except when the defect in the septum involves the



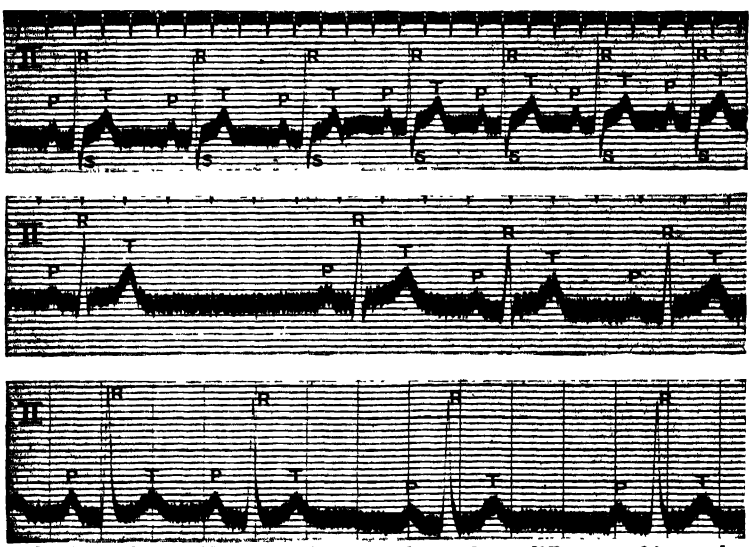


FIG. 57.—Electro-cardiogram from a case of transposition of the heart. All the deflections in lead II are inverted.

FIGS. 58, 59 and 60.—Electro-cardiograms from three different subjects showing sinus irregularity. The auricular and ventricular deflections are of normal form, but there is a variation in the length of the intervals between *T* and *P*.

auriculo-ventricular bundle and so gives rise to congenital heart-block. In congenital pulmonary stenosis the electro-cardiogram will reveal a marked right ventricular preponderance.

SINUS ARRHYTHMIA.—The electro-cardiogram of this rhythm may readily be identified (Figs. 58–60). There is merely a variation in the length of the diastolic periods, *i.e.* the intervals between *T* and *P* (see p. 885).

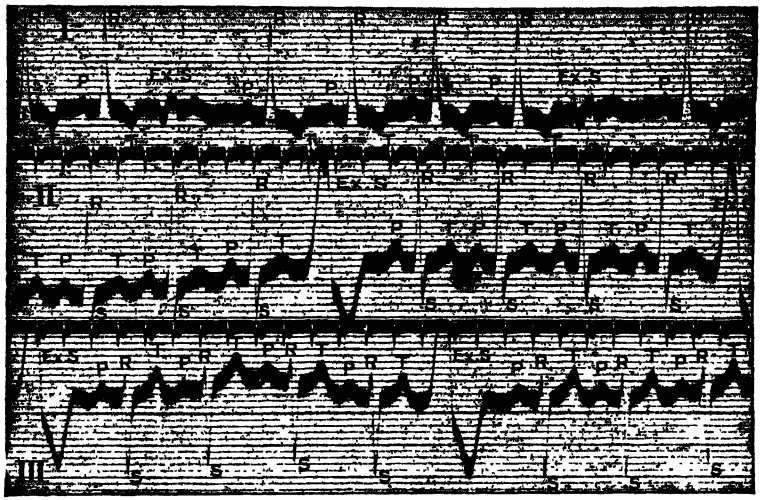

FIG. 61.—Electro-cardiogram showing ventricular extra-systoles, marked *Ex.S*. The corresponding *P* deflections are embedded in the diphasic variations. There is also inversion of *T* in lead I, and left-sided prepondesance.

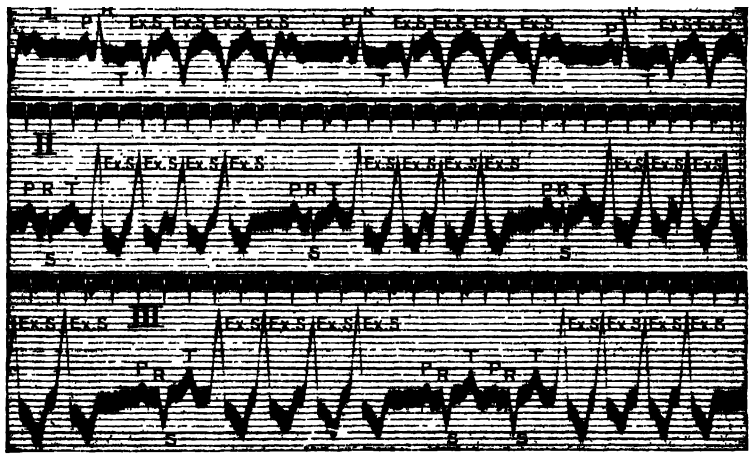

FIG. 62.—Electro-cardiogram showing rapid successions of ventricular extra-systoles. There is also inversion of *T* in lead I and left-sided preponderance.

EXTRA-SYSTOLES.—Extra-systoles may be readily recognised by means of the electro-cardiograph, and usually their site of origin.

In the ventricular variety (Figs. 61 and 62) the ventricular complex occurs

earlier than the anticipated time. As the ventricular contraction is ventricular in origin and therefore the wave of excitation travels along abnormal channels, the ventricular complex is wholly atypical: it is diphasic, and is of increased amplitude. It is of the same duration as that of the rhythmic contraction.

There are two main varieties of ventricular extra-systoles, and it is usually possible to differentiate them by means of the electro-cardiograph. In one, the ventricular complex consists of an upward, tall and pointed deflection, and then of a downward and broader deflection, in lead I; and of a downward, deep and pointed deflection, and then of an upward and broader deflection, in lead III. In the other variety, the ventricular complex consists of a downward, deep and pointed deflection, and then of an upward and broader deflection, in lead I; and of an upward, tall and pointed deflection, and then of a downward and broader deflection, in lead III. It was formerly thought, largely as the result of experiments in animals, that the first variety has its origin in the left ventricle or apical portion of the heart, and the second in the right ventricle or basal portion. Recent evidence has been adduced, based partly on direct observations on the exposed human heart, which strongly suggests that the opposite is the case. The direction of the deflections in lead II is usually the same as in lead III, but the reverse may be the case.

In the ventricular variety of extra-systoles, the auricle maintains its usual rhythm and contracts as the result of the normal stimulus from the sinus. It follows, therefore, that the corresponding *P* deflection appears at the anticipated time and is normal in form. But it is usually embedded in the ventricular complex, although it may be detected in this part of the electro-cardiographic curve in some cases, and occasionally is nearly separate.

If the ventricular extra-systole takes place after the normal auricular contraction, and the wave of contraction from the auricle has reached the ventricle and met that of the premature ventricular contraction in the ventricular wall, the ventricular complex of the premature contraction of the ventricle will present both typical and atypical features.

The site of origin of a ventricular extra-systole may occasionally be at one time in the basal or right portion of the ventricle, and at another in the apical or left portion, in the same subject.

A ventricular extra-systole is usually followed by a compensatory pause, which is complete. Sometimes, when the cardiac rate is slow, an interpolated extra-systole occurs.

In the auricular variety of extra-systole (Fig. 63) the *P* deflection takes place before the anticipated time. As the point of origin of the stimulus for contraction is at a site other than the sino-auricular node, almost always the *P* deflection is of abnormal form. The degree of difference depends upon the distance of the site of origin of the impulse from the sino-auricular node; and if near or at the node, *P* may be practically normal. Often the deflection is inverted (see lead II). The premature contraction of the auricle may take place so early as to coincide with the ventricular contraction of the preceding cycle, in which case *P* and the preceding *T* are superimposed. The *P*–*R* interval may be increased. The *P* deflection is usually followed by a premature ventricular complex. This is of typical form, since the ventricular contraction is of supra-ventricular origin and therefore the wave of excitation to the ventricle travels along the usual paths,

but it may be aberrant. Almost always aberrant ventricular beats are found only when there is diminished auriculo-ventricular conductivity. In some cases, the stimulus for contraction does not reach the ventricle at all, in which case the premature contraction of the auricle is not followed by a premature contraction of the ventricle—"blocked auricular extra-systole" (third extra-systole in lead I of Fig. 63).

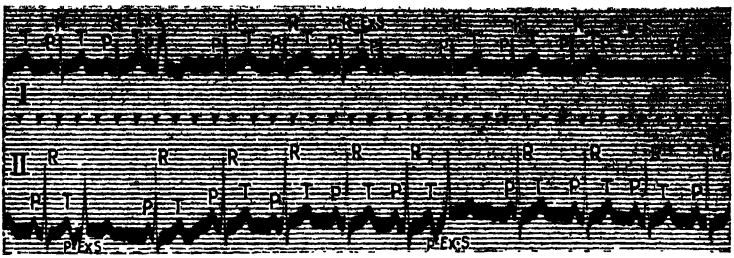

FIG. 63.—Electro-cardiogram showing auricular extra-systoles, marked *Ex.S.* The premature *P* deflections are of normal form in lead I, and of abnormal form—being inverted—in lead II. The premature ventricular complexes are of abnormal form. The third extra-systole in lead I is blocked.

In auricular extra-systole the compensatory pause is rarely complete.

In the auriculo-ventricular nodal variety of extra-systole (Fig. 64) there is prematurity of the *P* deflection and also of the ventricular complex. In cases in which the contraction of the auricle and ventricle is absolutely synchronous, the *P* deflection coincides with, and is embedded in, the *Q*, *R*, *S* complex (see lead II). When the contraction of the auricle begins before that of the ventricle, the *P* deflection precedes *R*, and the *P–R* interval is

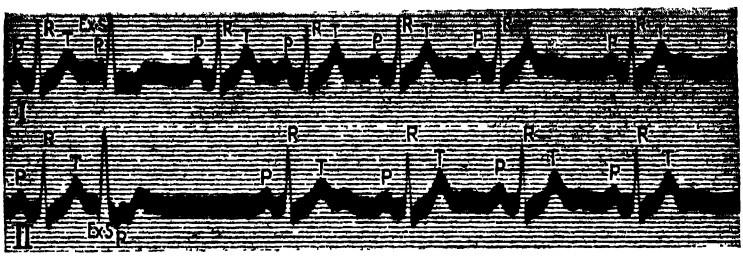

FIG. 64.—Electro-cardiogram showing auriculo-ventricular extra-systoles, marked *Ex.S.* In that of lead I the premature *P* deflection occurs before that of the ventricular complex, while that in lead II is embedded in the ventricular complex.

diminished (see lead I). When the auricular contraction commences after that of the ventricle, the *P* deflection follows the *R* deflection. When the *P* deflection is to be observed, as the auricular contraction is due to an impulse which arises at an abnormal point, it is almost always abnormal in form, often being inverted. As the ventricular contraction is supra-ventricular in origin, the ventricular complex is of typical form but may be aberrant.

In the auriculo-ventricular variety of extra-systole, the compensatory pause may, or may not, be complete.

Occasionally the beat immediately following an extra-systole arises from the same site as that of the premature contraction.

PAROXYSMAL TACHYCARDIA.—The first *P* deflection of the paroxysm is premature, and usually the paroxysm is followed by a long pause.

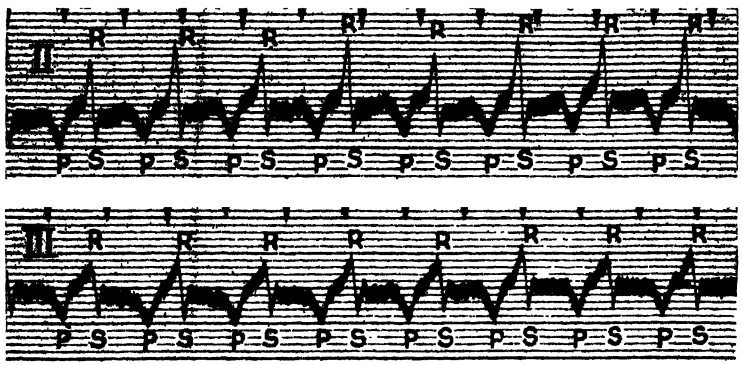

FIG. 65.—Electro-cardiogram showing the auricular variety of paroxysmal tachycardia.

There is no essential difference between the complexes of the individual beats during a paroxysm and those of single extra-systoles in the same individual.

In auricular paroxysmal tachycardia (Fig. 65) there is a rapid succession of *P* deflections occurring at regular intervals. As in the case of auricular extra-systoles, these are almost always of abnormal form, often being inverted. The contraction of the auricle may take place so early as to coincide with the ventricular contraction of the preceding cycle, in which

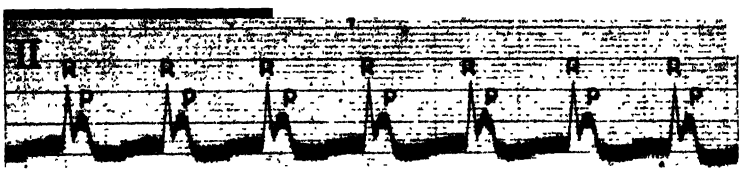

FIG. 66.—Electro-cardiogram showing the auriculo-ventricular nodal variety of paroxysmal tachycardia.

case *P* and the preceding *T* may be superimposed. The *P–R* interval may be increased. The *P* deflections are usually followed by ventricular complexes of the same form, or approximately so, as those preceding and following the paroxysm. There may be auriculo-ventricular block or bundle-branch block. In the latter case the ventricular complexes may resemble those of ventricular paroxysmal tachycardia. In this connection, in the differential diagnosis between the ventricular complexes of supra-ventricular and of ventricular origin, it is important to note whether any part of the *P* deflection

can be detected in the ventricular portion of the electro-cardiographic curve or not.

In auricular paroxysmal tachycardia, the rhythm is regular.

In auriculo-ventricular nodal paroxysmal tachycardia (Fig. 66) the electro-cardiogram is often difficult to determine. There is a rapid succession of auricular and also of ventricular complexes. In cases in which the contractions of the auricle and ventricle are absolutely synchronous, the *P* deflections coincide with and are embedded in the *Q*, *R*, *S* complexes. When the contractions of the auricle begin before those of the ventricle, the *P* deflections precede the *Rs*, and the *P–R* interval is diminished. When the auricular contractions commence after those of the ventricle, the *P* deflections follow the *Rs*. When the *P* deflections are to be observed, they are

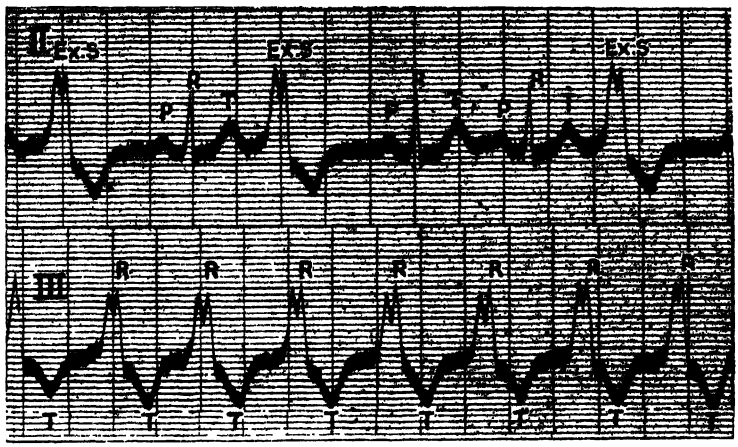

FIG. 67.—Electro-cardiogram of leads II and III. Lead II shows three isolated extra-systoles of ventricular origin. Lead III shows the ventricular variety of paroxysmal tachycardia, the complexes of which are of the same form as those of the isolated extra-systoles in lead II.

usually of atypical form, often being inverted. The ventricular complexes are of typical form but may be aberrant.

In auriculo-ventricular nodal paroxysmal tachycardia the rhythm may be regular or irregular.

In ventricular paroxysmal tachycardia (Figs. 67 and 68) there is a rapid succession of ventricular complexes. Usually each of these is of the same form as those of isolated extra-systoles arising in one ventricle (see p. 1010). In some cases, however, the point of origin of the beats is sometimes in one ventricle and at other times in the other, resulting in complexes of different form; and this may occur in the case of every other beat, so that complexes of different form alternate, which condition is sometimes called bi-directional ventricular tachycardia, and is of very serious significance. Sometimes the ventricular complexes are of indefinite form.

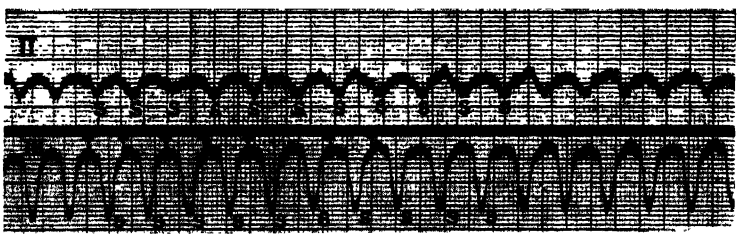
In the ventricular variety of paroxysmal tachycardia, the auricle generally maintains its usual rhythm, contracting as the result of an impulse arising

in the sino-auricular node. It follows, therefore, that the *P* deflections occur at the usual intervals and also are of normal form. They are generally embedded in the ventricular complexes, but in some cases they may be detected in this portion of the electro-cardiographic curve and occasionally they are nearly separate. In some cases, however, the ventricular rhythm gives rise to retrograde auricular beats, either with each ventricular contraction, or, less frequently, *i.e.* retrograde heart-block. Rarely there is auricular fibrillation, and more rarely auricular paroxysmal tachycardia, or auricular flutter.

In ventricular tachycardia, any existing irregularity of rhythm is usually so slight that it is detected only by means of graphic methods.

In the differential diagnosis of paroxysmal tachycardia by the electro-cardiograph, it is to be observed that, as the difference in the form of the complexes of the abnormal and the normal rhythms may be only slight it may be necessary to compare carefully the complexes of the paroxysm with those of the beats which either preceded or followed it—indeed, an analysis of either transition periods may be necessary.

AURICULO-VENTRICULAR NODAL RHYTHM.—In this condition, when the



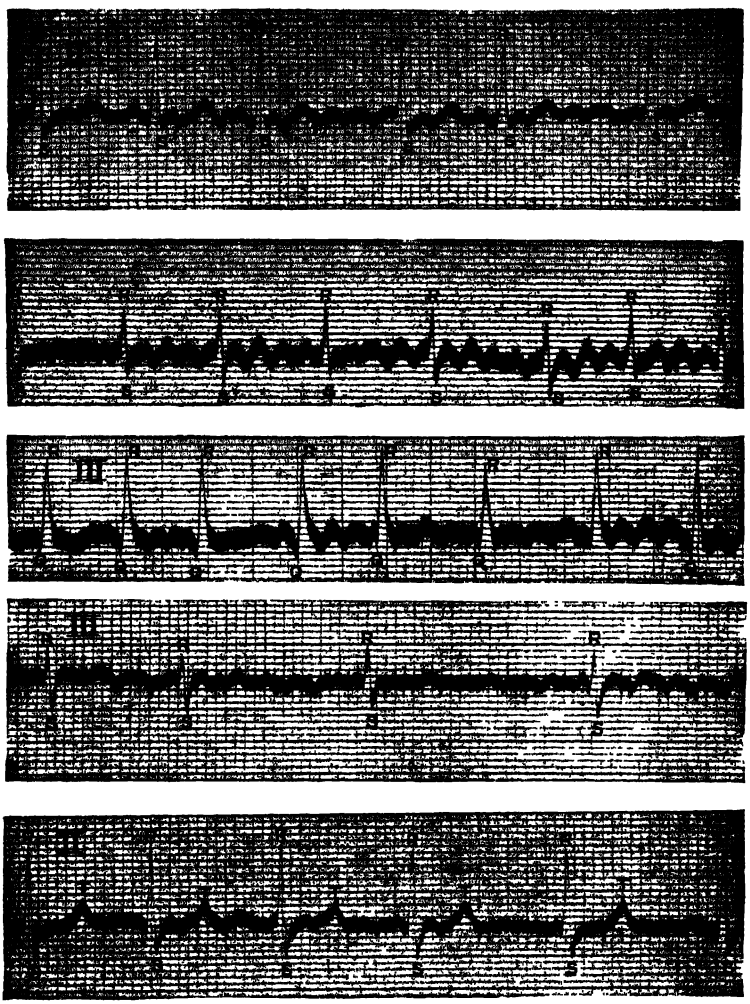


FIG. 68.—Electro-cardiogram of leads II and III showing the ventricular variety of paroxysmal tachycardia.

contractions of the auricle and ventricle are absolutely synchronous, the *P* deflections coincide with and are embedded in the *Q*, *R*, *S* complexes. When the contractions of the auricle begin before those of the ventricle, the *P* deflections precede the *Rs*, and the *P*–*R* interval is diminished. When the auricular contractions commence after those of the ventricle, the *P* deflections follow the *Rs*. When the *P* deflections are to be observed, they are usually of abnormal form, often being inverted. The ventricular complexes are of typical form but may be aberrant.

AURICULAR FIBRILLATION.—In auricular fibrillation the electro-cardiogram is characteristic (Figs. 69–73).

There is an absence of *P* deflections. There are, on the other hand, oscillations caused by the fibrillating auricle, called fibrillary waves, during ventricular diastole, at a rate ranging from 300 to 600, and usually about 450 times, per minute. They occur at irregular intervals, and their form and size vary, the latter being sometimes very minute and sometimes considerable. They are most evident in cases of slow cardiac action. They may coincide with the *T* deflections, in which case the outline of the latter is altered. Apart from the very rare cases in which complete auriculo-ventricular block is present, the ventricular rhythm is completely irregular, *i.e.* the *R* deflec-

tions occur at irregularly irregular intervals; their amplitude varies from cycle to cycle; and often there is no relationship between the length of a pause and the amplitude of the *R* deflection which follows it. When the

FIGS. 69–73.—Electro-cardiograms from cases of auricular fibrillation.

ventricular rate is slow or very rapid, this may be difficult to determine. As the ventricular beats are supra-ventricular in origin, the complexes are of typical form but they may be aberrant. There may be superadded ventricular extra-systoles, usually during the administration of one of the digitalis group of drugs (see p. 868).

In the differential diagnosis between the electro-cardiograms of auricular fibrillation and those of auricular flutter, in the former almost always the ventricular rhythm is completely irregular, while in the latter, it will be found that such is not the case, even when the rhythm is very irregular. Further, the deflections due to auricular systole in auricular flutter may be distinguished from the fibrillary waves in auricular fibrillation in that they are less frequent, rhythmic, of larger amplitude, and almost invariably of constant form and size.

Auricular Flutter.—In this condition it is of particular importance to analyse the three leads (Figs. 74–76). The *P* deflections may range from 180 to 360, the usual rate being about 300, per minute. In all the leads the deflections occur at regular intervals, and as soon as one terminates the next

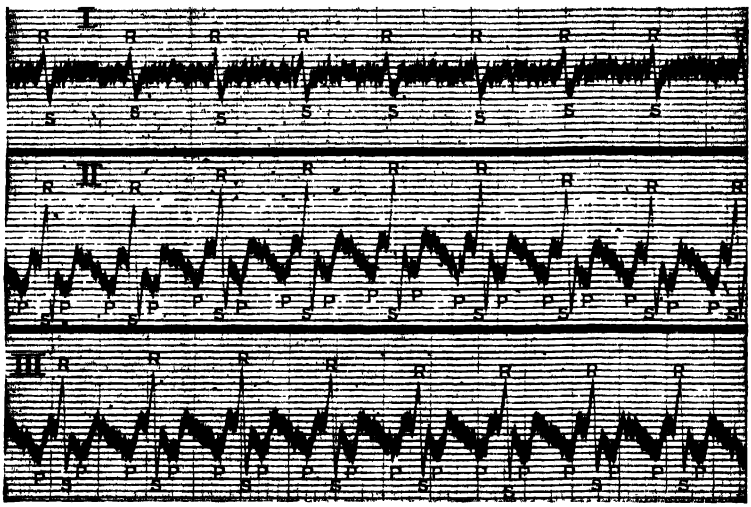

Fig. 74.—Electro-cardiogram from a case of auricular flutter, with 2 : 1 heart-block. The rate of the auricle is between 320 and 330 per minute.

one commences. In each lead of any given case they are almost invariably of constant form. In lead I the amplitude is comparatively small. As the impulse arises at an abnormal point, the deflections are atypical in form. The ascending limb is rather sharp, and the descending more gradual, and the summit may be dome-shaped. It is difficult to say at what part the deflection begins. As the ventricular complexes are supra-ventricular in origin, they are of typical form. They are superimposed upon the *P* deflections, modifying their outline. In some cases *T* may be detected. Excepting in the very rare cases of 1 : 1 rhythm, in which event there is an equal number of *P* deflections and ventricular complexes, there are two or more *P* deflections to each ventricular complex, according to the degree of auriculo-ventricular block (see p. 900). When the response of the ventricle to auricular contraction is at irregular intervals, the ventricular rhythm may be even very irregular.

It is necessary to differentiate the electro-cardiograms of auricular flutter from those of auricular fibrillation. This is dealt with on p. 1016.

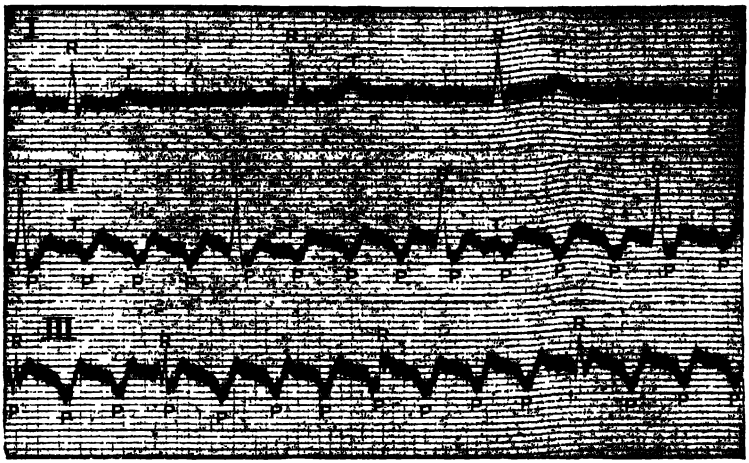

FIG. 75.—Electro-cardiogram from a case of auricular flutter, with 4 : 1 heart-block.

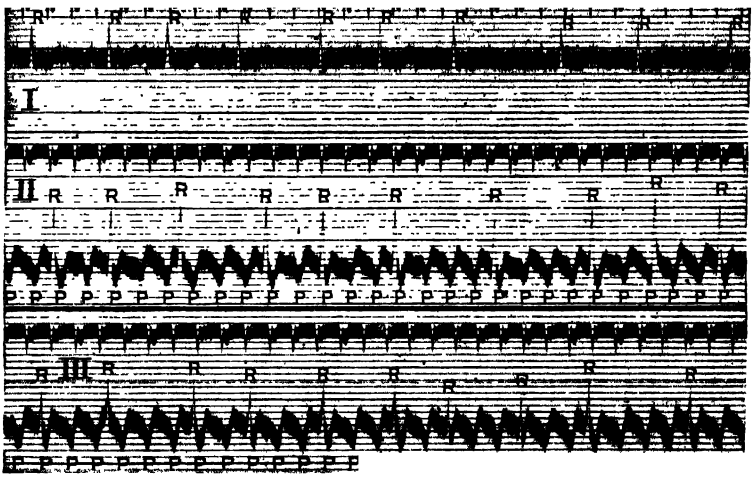

FIG. 76.—Electro-cardiogram from a case of auricular flutter. The auriculo-ventricular ratio is sometimes 2 : 1, at others 3 : 1, and at others again 4 : 1. The response of the ventricle to auricular contraction being at irregular intervals, there is irregularity of the ventricular rhythm.

VENTRICULAR FIBRILLATION.—The ventricular complexes are replaced by oscillations, occurring at very rapid and irregular intervals, and their form and size vary.

SINO-AURICULAR BLOCK.—In this condition there is an absence of both the auricular and ventricular complexes during an abnormally long pause. (See p. 904 and Fig. 77.)

AURICULO-VENTRICULAR BLOCK.—In the first grade (leads I and III of Fig. 78) there is merely an increase of the *P–R* interval, it exceeding 0·18

FIG. 77.—Electro-cardiogram showing an abnormally long pause due to sino-auricular block.

second. It may be increased to such a degree that *P* coincides with the preceding *T*.

In the second grade (lead II of Fig. 78) the *P* deflections are found at regular intervals and are of typical form. Sometimes the *P* deflections are not followed by ventricular complexes, the frequency of such depending

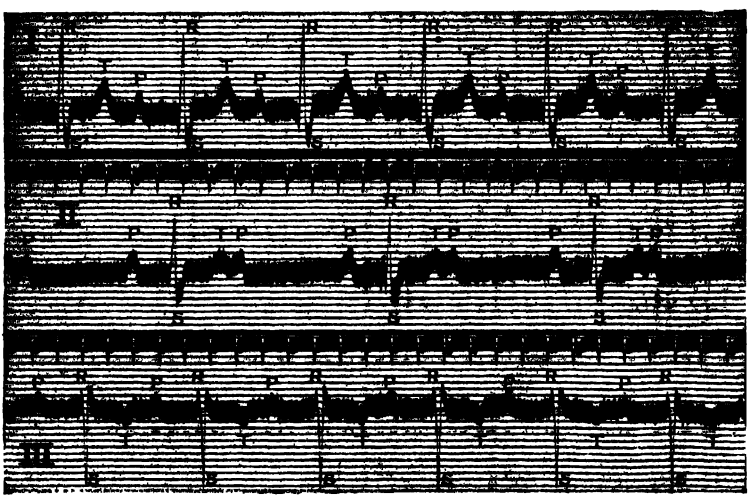

FIG. 78.—Electro-cardiogram showing partial heart-block. In each lead there is an increase of the *P–R* interval, and in lead II there is also continuous 2 : 1 rhythm, every other stimulus from the auricle failing to reach the ventricle. There is also inversion of *T* in lead III and left-sided preponderance.

upon the degree of block, as described on p. 905. Unlike complete heart-block, on each occasion the ventricular complex is preceded by a *P* deflection. In the case of dropped beats, almost always there is a progressive increase of the *As–Vs* interval preceding and a progressive shortening of the interval following each dropped beat, so that the prolonged pause during a dropped beat is not equal to two regular pulse-beats. As the ventricular beats

are of supra-ventricular origin, the ventricular complexes are of typical form.

In complete heart-block (Fig. 79) the *P* deflections are found at regular intervals, and are of typical form. They are more frequent than the ventricular complexes. In addition, the time-relation between the *P* deflec-

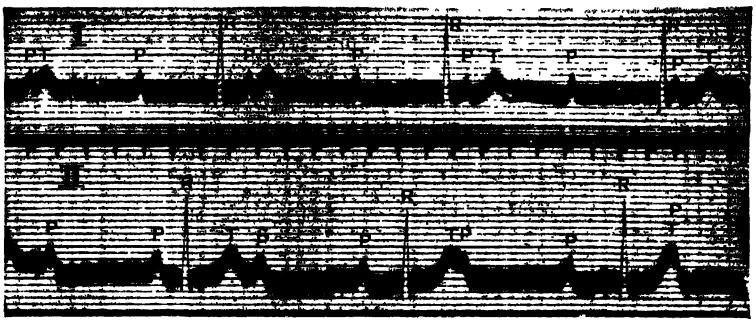

FIG. 79.—Electro-cardiogram of leads I and II showing complete heart-block, or dissociation of the auriculo-ventricular rhythm, the auricles and ventricles beating independently of each other.

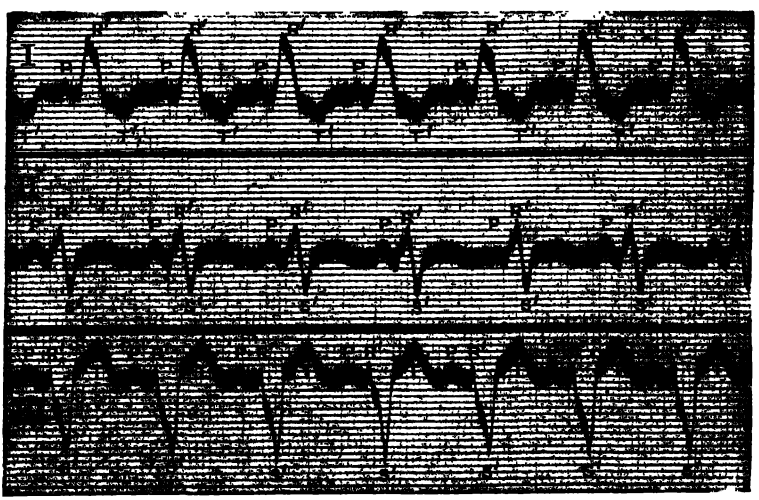

FIG. 80.—Electro-cardiogram showing a lesion of the left main branch of the auriculo-ventricular bundle (new nomenclature).

tions and the ventricular complexes is a constantly varying one, the former at one time preceding, at another following, and sometimes, again, coinciding with the latter. In the last case the *P* deflection is superimposed upon the ventricular complex. As the ventricular beats are of supra-ventricular origin, the ventricular complexes are of typical form. Sometimes there are superadded ventricular extra-systoles.

BUNDLE-BRANCH BLOCK.—A lesion of either of the two branches of the auriculo-ventricular bundle may be recognised by means of the electro-cardiograph (Figs. 80 and 81).

The ventricular complex is diphasic and of increased amplitude. The initial group of deflections (*Q*, *R*, *S*) is of increased duration, exceeding one-tenth second and comprising more than one-third of the whole complex, and usually exhibits pronounced or irregular notching. The terminal deflection (*T'*) points in the opposite direction to the initial group of deflections in leads I and III. In lead II, *Q*, *R*, *S* is usually of less amplitude and is often diphasic; *T'* may point in either direction. In the diphasic ventricular complexes of leads I and III there is usually no iso-electric period between *Q*, *R*, *S* and *T*. The *P*–*R* interval may be increased.

Two types of curves may be recognised: (1) The common type, in which

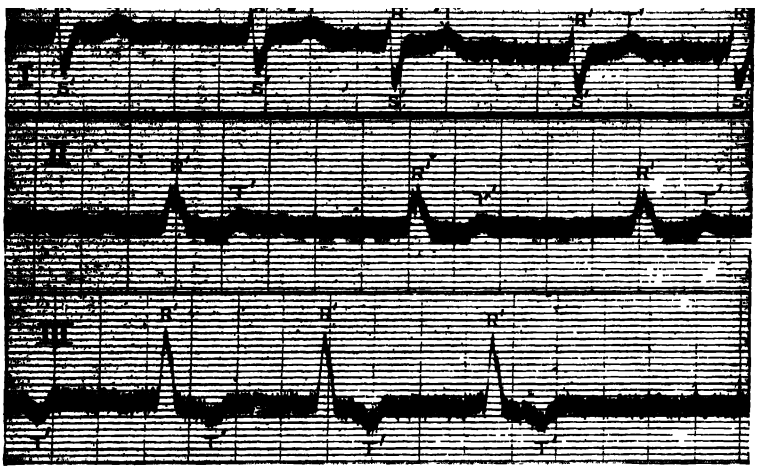

FIG. 81.—Electro-cardiogram showing a lesion of right main branch of the auriculo-ventricular bundle (new nomenclature). There is also auricular fibrillation.

there is a large *R'* in lead I and a large *S'* in lead III, *T'* pointing downwards in lead I and upwards in lead III. (2) The rare type, in which there is a large *S'* in lead I, and a large *R'* in lead III, *T'* pointing upwards in lead I and downwards in lead III. It was formerly supposed that the first type was indicative of right bundle-branch block, and that the second signified left bundle-branch block. It is now believed that the opposite is the case.

It is necessary to distinguish between a lesion of the left or right main branch (new nomenclature) and preponderance of the left or right ventricle respectively. The distinguishing features are that in bundle-branch block the initial group of deflections is of increased duration and usually exhibits pronounced or irregular notching, and *T* points in the opposite direction to the main initial deflection in leads I and III. As already noted, increased duration of the *Q*, *R*, *S* complex may be met with in extreme preponderance of either ventricle. But taking cases of preponderance as a whole, the

period of time is materially less. In addition, pronounced or irregular notching does not occur, and T is not of increased amplitude and, apart from exceptional cases, points in the same direction.

FUNCTIONAL BUNDLE-BRANCH BLOCK.—A condition, which is rare, in which there is increased duration of the Q, R, S group of deflections together

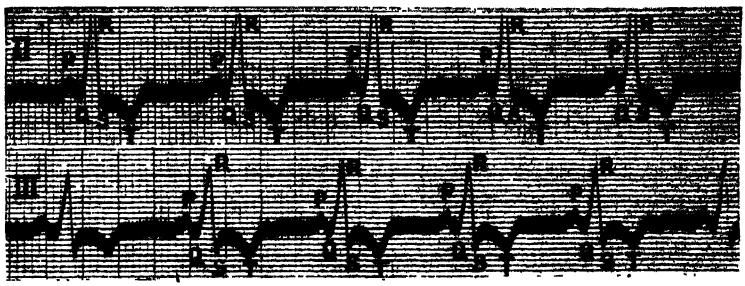

FIG. 82.—Electro-cardiogram showing functional bundle-branch block.

with a diminished P–R interval (Fig. 82) has been termed functional bundle-branch block.

ARBORIZATION OR INTRA-VENTRICULAR BLOCK.—The initial group of deflections is of increased duration and usually exhibits pronounced or irregular notching, and is of low voltage (Fig. 83). Some believe that occasionally the T deflection points in the opposite direction to the initial

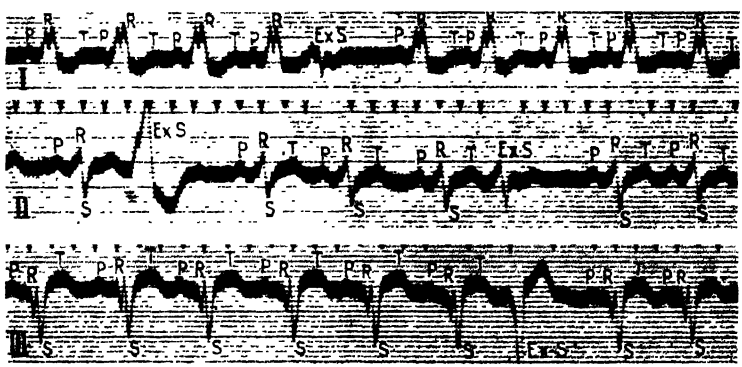

FIG. 83.—Electro-cardiogram showing arborization block. There is an extra-systole, marked Ex.S, in lead I, two extra-systoles in lead II, and one in lead III.

deflection in leads I and III. Even if such should be the case, its form is not so abnormal.

It should be pointed out that some writers are of opinion that the electro-cardiogram just described indicates a delay of the wave of excitation along the right or left main division of the auriculo-ventricular bundle, *i.e.* incomplete or partial bundle-branch block.

ALTERNATION OF THE HEART.—This may sometimes be recognised by means of the electro-cardiograph, by an alternation in the amplitude of the deflections due to the contraction of the ventricle (Fig. 84). Both the *R* and *T* waves may be affected, or one more than the other. It should be noted that alternation of the heart is sometimes shown in a sphygmogram without any corresponding evidence in an electro-cardiogram, while rarely the opposite holds good. It should be further noted that the alternation in a sphygmogram and electro-cardiogram does not always correspond ; *i.e.* the smaller ventricular deflections correspond with the larger pulse-wave.

ANGINA PECTORIS.—Left-sided preponderance is usual. In a proportion of cases the ventricular complexes are abnormal. Most varieties of these

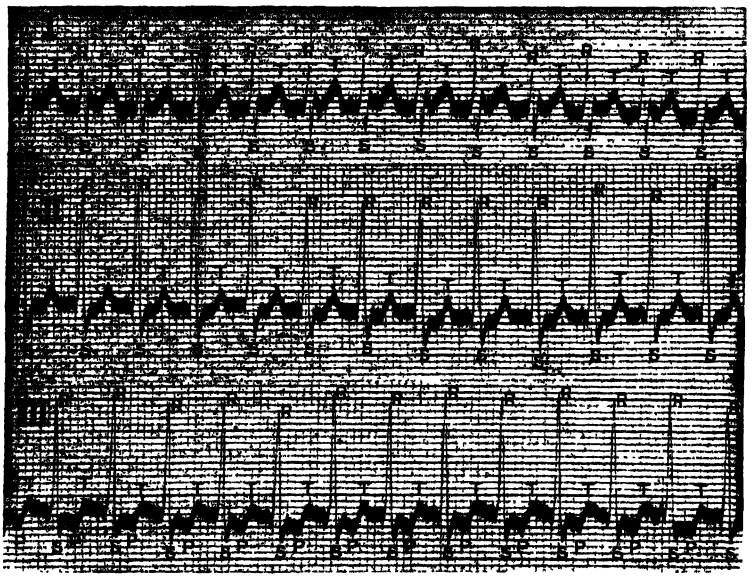

FIG. 84.—Electro-cardiogram from a case of paroxysmal tachycardia. There is alternation in the amplitude of the *R* deflections.

abnormalities may be met with, including flattening or inversion of *T* in lead I or II, or both ; increased duration, and notching of the *Q*, *R*, *S* group of deflections ; bundle-branch block ; and a large *Q* deflection in lead III (see p. 1025). There may be extra-systoles and some degree of heart-block Other abnormalities of rhythm are exceptional. The changes in the ventricular complexes may be of considerable value in doubtful cases. Negative findings, on the other hand, are of no importance.

Transient modifications of the electro-cardiograms similar to those of coronary occlusion with infarction have been observed in some cases of angina pectoris during the attacks. Such are of much diagnostic significance.

CORONARY OCCLUSION WITH INFARCTION OF THE HEART.—Electro-cardiograms of this disease are usually characteristic and of great diagnostic value. They are as follows :

Within a few hours there is usually a deviation of the *R–T* or the *S–T* segment. This portion of the curve commences from the *R* or *S* deflection either above or below the iso-electric level and proceeds in a more or less horizontal direction, resulting either in a plateau-shaped elevation or in a depression respectively. This alteration is generally most noticeable in

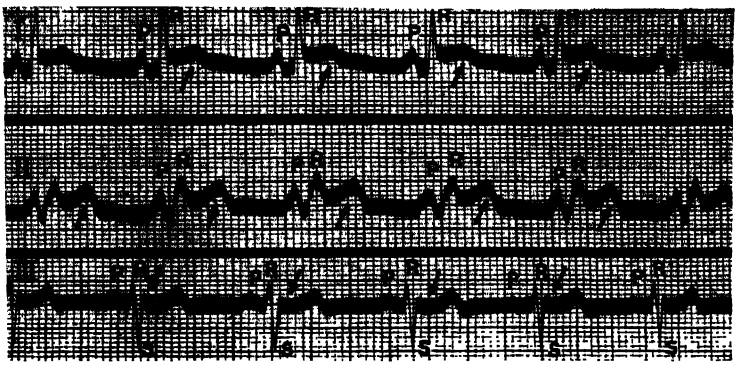

FIG. 85.—Electro-cardiogram from a case of the T^1 type of infarction of the heart taken early after the onset of symptoms. The *R–T* portion of the curve commences above the zero level in leads I and II, and slightly below the zero level in lead III, as indicated by arrows.

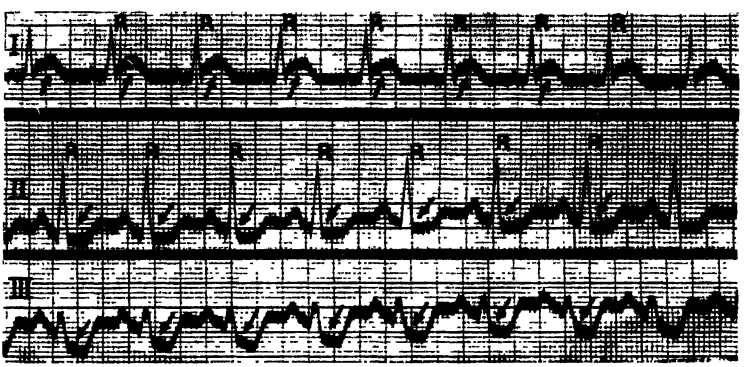

FIG. 86.—Electro-cardiogram from a case of the T^1 type of infarction of the heart taken early after the onset of symptoms. The *R–T* portion of the curve commences above the zero level in lead I, and below the zero level in lead III and rather so in lead II, as indicated by arrows.

leads I and III. In this event, the corresponding portions of the curves in these leads are divergent. Thus, if there is *R–T* elevation in lead I there is *R–T* depression in lead III (Figs. 85 and 86); and *vice versa* (Figs 87 and 88). Sometimes the deviation of the *R–T* segment is best observed in leads III and II, or in leads I and II; or the alteration may be present in one lead only. The foregoing features are perhaps pathognomonic of the condition.

After a few days or more, the *R–T* portion of the curve gradually returns to the iso-electric level, and the *T* deflections gradually reappear. The latter assume a direction opposite to that to which the *R–T* segments were

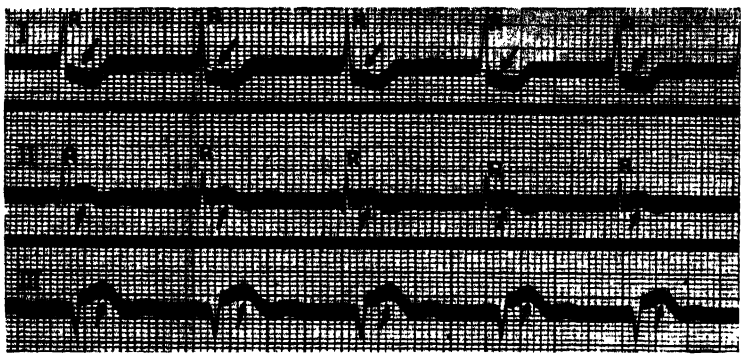

FIG. 87.—Electro-cardiogram from a case of the T^3 type of infarction of the heart taken early after the onset of symptoms. The *R–T* portion of the curve commences above the zero level in lead III and slightly so in lead II, and below the zero level in lead I, as indicated by arrows.

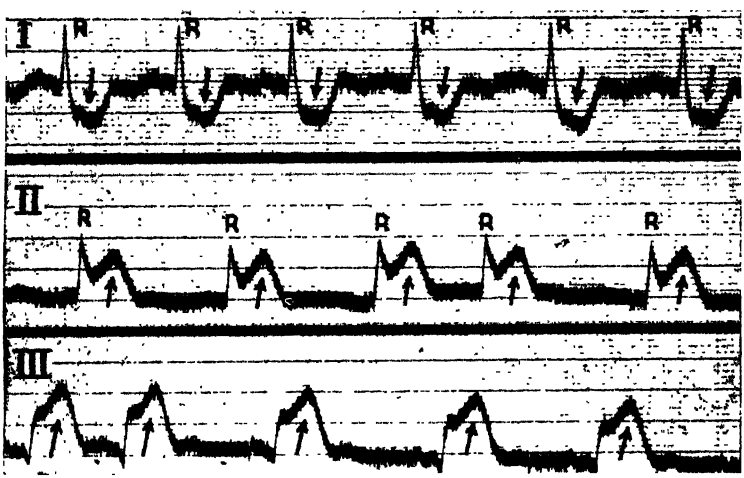

FIG. 88.—Electro-cardiogram from a case of the T^3 type of infarction of the heart taken a few hours after the onset of symptoms. The *R–T* portion of the curve commences below the zero level in lead I and above the zero level in leads II and III, as indicated by arrows.

previously deviated. Thus, inversion of the *T* deflections follows elevation of the *R–T* segments, and upright *T* waves follow depression of the *R–T* segments. (Figs. 89–91.) The *T* deflections are usually sharply defined, and their amplitude is often large. The *R–T* intervals preceding the

altered *T* waves frequently exhibit convexity or concavity. The foregoing features are not so characteristic as are those of the first stage, but, taken together with the clinical features, they afford strong corroborative evidence of the disease.

In both stages, sometimes there is diminished amplitude and increased duration of the initial group of ventricular deflections (*Q*, *R*, *S*), and the latter is generally associated with notching or splintering.

There are various types of curves, the two commonest being: (1) Lead I shows *R–T* elevation and, later, inversion of the *T* deflections; and in lead III, the *R–T* segments are depressed, with the subsequent development of upright *T* waves. (Figs. 85, 86 and 89). (2) Lead III shows *R–T* elevations and, later, inversion of the *T* deflections; and in lead I, the *R–T* segments are depressed, with the subsequent development of upright *T* waves (Figs. 87, 88, 90 and 91).

The first type, which is the more common, is associated with occlusion

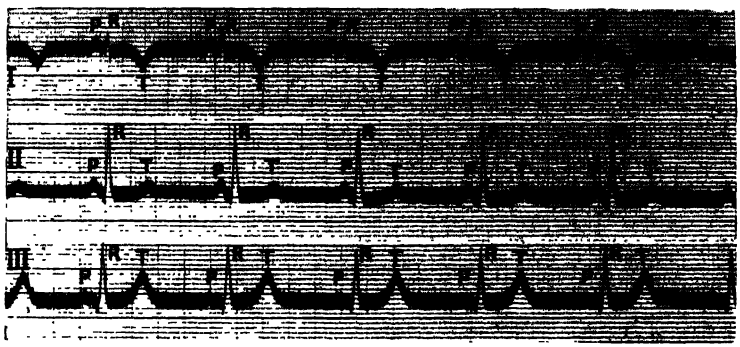

FIG. 89.—Electro-cardiogram from a case of the T^1 type of infarction of the heart. The *T* deflections in lead I are inverted, and are rather sharply defined and of increased amplitude. Those in lead III are upright, and are sharply defined and of increased amplitude.

of the descending branch of the left coronary artery and infarction of the wall of the left ventricle near the apex, especially the anterior part, and the adjacent part of the interventricular septum; and is termed the T^1 type. The second is associated with occlusion either of the right coronary artery or the circumflex branch of the left and infarction of the posterior wall of the left ventricle near the base; and is designated the T^3 type.

In both types of curves the *T* deflections in lead II are often slightly inverted or flattened.

Some changes in the *T* deflections towards the normal usually supervene within a few weeks or months, and ultimately the *T* deflections in all leads may become normal, but sometimes those in one lead remain inverted and sharply defined, and even these changes are very suspicious.

A large *Q* deflection in lead III (see Figs. 90 and 91) is often a noticeable feature of infarction of the posterior wall of the left ventricle, either recent or old. It is to be noted, however, that it may also occur in other conditions (see p. 1003).

Lead IV is particularly valuable in occlusion of the descending branch of the left coronary artery, *i.e.* the T^1 type. This lead alone may be affected, while in some cases the changes are more evident, or occur earlier and last longer than in the three other leads. They resemble those of lead I of this type. Thus, there is elevation of the *R–T* intervals, and subsequently in-

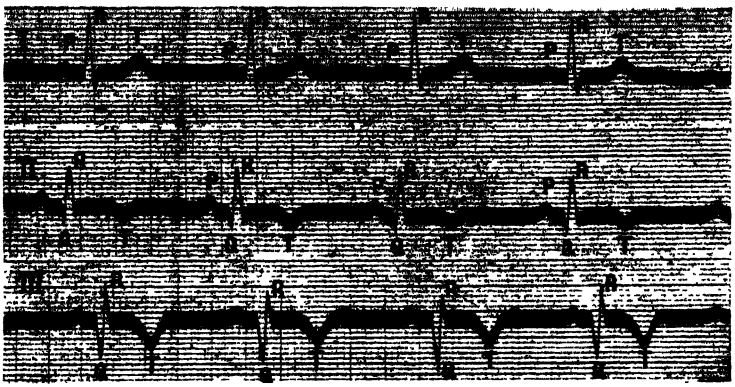

FIG. 90.—Electro-cardiogram from a case of the T^3 type of infarction of the heart. The *T* deflections in lead II are inverted. Those in lead III are inverted, and are sharply defined and of increased amplitude. There is a large *Q* in lead III.

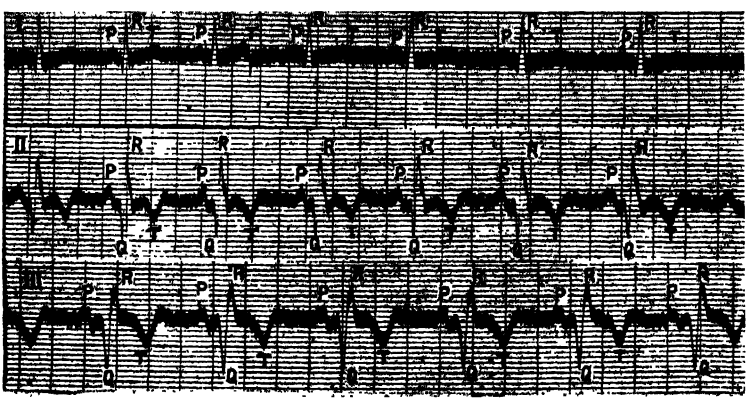

FIG. 91.—Electro-cardiogram from a case of the T^3 type of infarction of the heart. The *T* deflections in leads II and III are inverted, and are sharply defined and of increased amplitude. There is a large *Q* in leads III and II.

verted *T* waves. (Figs. 92 and 93.) Lead IV is of less value in infarction of the posterior wall of the left ventricle, *i.e.* the T^3 type. There may be no changes, or if present they are less marked. If there are changes, they generally resemble lead I of this type. Thus, there is depression of the *R–T* intervals and, later, upright *T* deflections. The latter are of increased amplitude, and may be huge. (Fig. 94.)

The foregoing changes in the electro-cardiograms of coronary occlusion with infarction of the heart are not constant. But they are frequent, and when they do occur are of great diagnostic value. It is necessary to point out that it is the successive changes in the curves which are especially

FIG. 92.—Electro-cardiogram of the fourth lead from a case of the T^1 type of infarction of the heart. There is R–T elevation, as indicated by arrows, and inversion of T. There is also a large Q.

important. For this reason, serial records taken over a period of time are of much greater value than a single one, for in cases in which the latter does not reveal the characteristic changes, later curves may do so. It is unusual to find an absence of these changes during the whole of the first two weeks

FIG. 93.—Electro-cardiogram of the fourth lead from a case of the T^1 type of infarction of the heart. There is slight R–T elevation, and the T deflections are inverted, sharply defined and of increased amplitude. There is also a large Q.

after the onset of symptoms, though transient changes may have disappeared in later electro-cardiograms.

In conclusion, it is to be noted that a similar deviation in the R–T (or S–T) interval has also been recorded in rheumatic carditis, pericardial

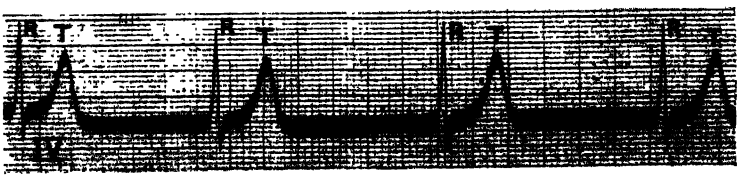

FIG. 94.—Electro-cardiogram of the fourth lead from a case of the T^3 type of infarction of the heart. The T deflection is positive, sharply defined and huge.

effusion, uræmia, and pneumonia. The clinical features of these conditions, however, do not resemble those of coronary occlusion.

It has been pointed out that transient changes in the electro-cardiograms similar to those of coronary occlusion have been observed during attacks of angina pectoris.

Low Voltage.—The term low voltage is used when no part of the *Q*, *R*, *S* complex exceeds five millimetres in the three leads. It is almost always of

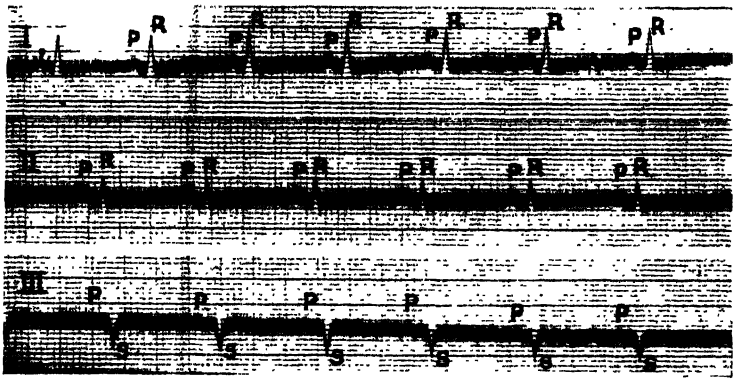

Fig. 95.—Electro-cardiogram from a case of hypothyroidism. The *T* deflections are absent in the three leads; and there is also diminished amplitude of the *Q*, *R*, *S* complex.

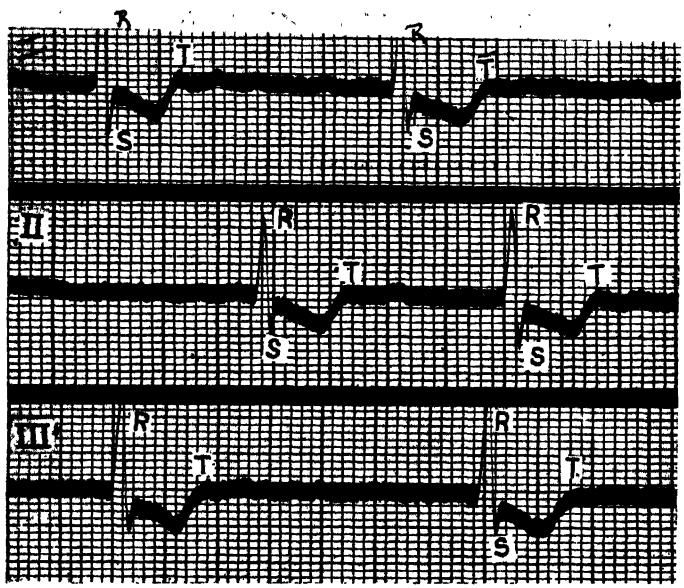

Fig. 96.—Electro-cardiogram from a case of auricular fibrillation fully under the influence of digitalis.

pathological significance, and may be met with in marked chronic myocardial disease, severe congestive failure from any cause, coronary occlusion, pericardial effusion, and hypothyroidism. In the last named there are also

changes in the other deflections (see below). As stated on p. 1021, low voltage is one of the various features found in arborization or intraventricular block.

HYPOTHYROIDISM.—The *T* deflections are flattened or inverted in the three leads; and frequently there is also diminished amplitude of the *Q*, *R*, S complex. See Fig. 95.

THE EFFECT OF DIGITALIS.—Electro-cardiograms of patients fully under the influence of digitalis may show depression of the *R–T* interval with flattening or inversion of the *T* deflections (see Fig. 96). This should be distinguished from the *R–T* deviation due to coronary occlusion. In the former the corresponding portions of the curves always point in the same direction; while in the latter usually they point away from each other in leads I and III.

FREDERICK W. PRICE.

DISEASES OF THE BLOOD VESSELS

The term arterio sclerosis, which means no more than arterial hardening, has led to much confusion as it has been employed by various authors in different senses to describe different pathological conditions of the arteries. Thus, it has been used to comprise the following conditions:

(*a*) Diffuse hyperplastic sclerosis, characterised by intimal hyperplasia and hypertrophy of the media;

(*b*) Degeneration of the middle coat of the artery, known as Mönckeberg's medial sclerosis, in which lime salts are deposited more or less symmetrically in rings around the artery; and

(*c*) Arterial degeneration of the intima, known as atheroma, or, because of the tendency to calcification, as atherosclerosis.

Or it is confined to the first and second. Or it is restricted to the first. Or it is employed to include the three mentioned above and, in addition, arterial inflammation, which when chronic is most often the result of syphilis but may be caused by other infections. Or, finally, it is employed by a few writers to include even other pathological conditions, such as infiltration. It is, therefore, clear that the term arteriosclerosis should not be used except in a very general sense.

It is proposed to adopt the following classification of diseases of the arteries:

(i) Arterial inflammation
- (*a*) Acute arteritis
- (*b*) Chronic arteritis
- (*c*) Thrombo-angiitis obliterans
- (*d*) Polyarteritis nodosa or periarteritis nodosa

(ii) Diffuse hyperplastic sclerosis
(iii) Mönckeberg's medial sclerosis
(iv) Fatty Degeneration of the Media
(v) Atheroma (Atherosclerosis)
(vi) Other Degenerations allied to atheroma
(vii) Arterial infiltration.

And the following will be dealt with separately: (1) The syndrome of intermittent claudication, caused by several of the foregoing pathological conditions; (2) Aneurysms, whether (*a*) saccular, most frequently caused by syphilis; (*b*) aneurysmal dilatation, most often due to atherosclerosis; or (*c*) the less common forms of aneurysm.

ARTERIAL INFLAMMATION

The arteries may be infected from their intima, either by micro-organisms settling on the surface or by the arrest of an infective embolus within the lumen. They may also be infected by micro-organisms reaching the media or adventitia through the vasa vasorum or by direct inward spread of inflammation from the surrounding tissues.

Acute Arteritis

Acute arteritis was formerly described as a common event in many diseases, the staining of the intima being mistaken for inflammation. Acute inflammation of the arteries is, however, a rare disease, and is usually met with as a complication in the acute infections. The intima of the aorta may be infected in cases of septicæmia and pyæmia, and most commonly in cases of progressive septic endocarditis, when the organisms usually found are streptococci. Vegetations may be seen upon the intima and the inflammation rapidly involves the subjacent coats. Occasionally the aorta may be infected in a septicæmia or pyæmia, through embolism of the vasa vasorum, or the ascending aorta may be infected by spread through the vessel wall from a pericarditis. The wall of the aorta may rupture, or an aneurysm be formed, but this is rare. Acute multiple arteritis is most frequently seen as a sequel of typhoid fever, but cases have been observed after small-pox, scarlet fever, influenza, and pneumonia. In many cases the organisms of the disease have been found in the vessel wall.

Symptoms.—The symptoms depend upon the vessels affected. In the case of the femoral artery, there may be severe pain in the course of the vessel with sometimes redness and swelling in the part affected. The pulse below is obliterated. The limb becomes pale and cold, and then livid. Gangrene may or may not follow; it depends upon the rapidity with which the vessel is blocked. In some cases where the onset is severe and the symptoms suggest that gangrene will follow, the circulation improves and colour returns to the limb. In other cases, several of the arteries may be infected at the same time, with high fever and symptoms of an acute infection. Some cases of cerebral thrombosis in which a young or middle-aged patient makes a good recovery and lives for twenty or thirty years without any other vascular catastrophes are probably of this type.

Prognosis and Treatment.—In acute arteritis treatment, other than rest and general and local measures for the relief of pain, is of little avail. The condition is a very severe one. If the artery involved is a large one, every effort should be made to avoid infectious gangrene, and in some cases a surprising return of circulation may be observed.

Chronic Arteritis

Ætiology.—Acquired syphilis is by far the most common cause of chronic arteritis, and less frequently congenital syphilis. Tuberculous endarteritis is not uncommon in the small pulmonary arteries and in the arteries of the brain in tuberculous meningitis. Endarteritis obliterans may also be caused by infection with pyogenic organisms of a subacute or chronic type. Moreover, changes in the adventitia of the small arteries are also found in polio-encephalo-myelitis and in encephalitis lethargica.

Pathology. — Chronic arteritis is a focal affection, and is found in muscular and elastic arteries of all calibres. It is common in the aorta and large elastic arteries, and it also frequently attacks the small arteries. The large muscular arteries, however, are but rarely affected by syphilis. Chronic inflammation of the arteries has been divided into—(1) Endarteritis, where the intima is affected; (2) mesarteritis; and (3) periarteritis, where the external coat is involved. In the great majority of cases of inflammation of the smaller arteries all coats are involved. The muscular and elastic fibres tend to be destroyed and this may result in direct rupture. The changes in the intima are very conspicuous. Its layers become very much thickened by inflammatory infiltration and proliferation. In the early stages round cells are seen, and later spindle-shaped fibroblasts, definite granulation being thus formed, while in cases of syphilis plasma cells and eosinophil leucocytes are often present. The result of this thickening in such small arteries is to narrow the vessel, and the condition is often termed endarteritis obliterans. The lumen may finally become completely blocked, leading in the brain to cerebral softening, and in other tissues to fibrosis. The adventitia is also greatly thickened in chronic syphilitic arteritis and consists of inflamed tissue infiltrated by lymphocytes, plasma cells, and occasional eosinophil leucocytes.

Syphilis of the aorta or *syphilitic mesaortitis* is a focal inflammation, but it may implicate almost the whole length of the aorta. The inflammation extends from the adventitia. The vasa vasorum proliferate and in most cases pass into the intima. About these vessels is a zone of granulation tissue, usually consisting only of plasma cells, lymphocytes, eosinophil leucocytes, and fibroblasts, but occasionally there are gummata with giant cells. Endarteritis of the vasa vasorum is found only in the more intense reactions. The elastic fibres of the media are completely destroyed in the areas of granulation tissue; occasionally the media is necrosed between areas of granulation tissue. The *Sp. pallida* has been demonstrated in the lesions. The intima of the aorta is usually thickened over the areas of inflammation, and this thickening has been in the past confused with the degeneration of the intima that we know as atheroma. The inflammatory thickening of the intima due to syphilis can, in its earlier stages, be distinguished by the naked eye from atheromatous thickenings by its sharper demarcation, pearly colour, rubber-like consistency, crenated outline, pitted surface, and freedom from fatty degeneration. The weakening of the vessel wall on account of the replacement of the middle coat frequently results in dilatations, varying in size from minute stellate patches to large aneurysms. The scarring and pitting are due to fibrous tissue replacing the inflamed media and are characteristic. In the later stages atheroma usually occurs

in the thickened intima over the areas of inflammation; also syphilitic mesaortitis and primary atheroma may co-exist, especially in later life.

The *coronary* circulation is often found affected in these cases, with the result that there are attacks of angina pectoris. Owing to the mesaortitis of the ascending aorta, the orifices of the coronary arteries become narrowed or blocked, but the disease does not spread far down the arteries, in this way providing a striking contrast with atheroma. It may cause extensive necrosis or fibrous patches in the myocardium, and the heart is not uncommonly enlarged. Frequently the aortic ring has expanded, or the aortic valves have become involved by the syphilitic inflammation, so that aortic regurgitation is a common sequel.

The *arteries of the brain* are frequently involved by syphilis, which causes endarteritis obliterans and consequent cerebral softening. This change is also present in syphilitic meningitis, where the syphilitic inflammatory reaction is more intense. The kidneys are but rarely affected, though occasionally gummata are found. The eyes are not infrequently attacked and a condition of syphilitic choroido-retinitis may be seen on ophthalmoscopic examination. In other organs, such as the liver and testicle, gummatous necrosis, followed by fibrous changes, is found. In rarer instances the trachea and lungs are affected.

Symptoms.—The symptoms that result from syphilitic vascular disease depend upon the organ affected.

In the aorta, aneurysm is a common result from syphilis. Aortic regurgitation, with its usual effect on the heart, is even more common. The symptoms of necrosis or fibrosis of the myocardium are severe anginal pains, often resulting in sudden death. Occasionally the heart muscle may give way, with the usual signs of chronic cardiac failure. If the brain is affected by arterial thrombosis, the symptoms depend upon the area affected; hemiplegia, aphasia, and hemianopia may all result. Albuminuria is quite uncommon in syphilitic vascular disease. Iritis may be present, and more commonly choroiditis, in which white patches surrounded by pigmented areas give a striking appearance to the fundus oculi. The optic disc is often white and atrophied. In syphilitic meningitis, œdema of the optic papilla is often present. The radial artery is practically always normal to the touch in cases of syphilitic vascular disease.

Course.—The course of syphilitic arterial disease is very variable. The symptoms resulting from endarteritis and subsequent thrombosis in medium-sized arteries such as the cerebral, are generally present in the acute secondary stage, from 2 to 5 years from the date of infection, but the vascular disease may exist with exacerbations all through life, and the important and characteristic cardiovascular changes in the first part of the aorta generally follow 15 to 25 years after the original infection.

Prognosis.—The prognosis in cerebral syphilitic vascular disease is on the whole good, if the condition be taken early enough and treated properly. It has to be remembered, however, that vascular syphilis is often complicated by parenchymatous syphilis, where the spirochætes are not only found in the walls of the vessels, but also in the cerebro-spinal tissues themselves, and this complication certainly increases the gravity of the condition. In the later cardiovascular syphilis the prognosis is bad unless the diagnosis is made early before any serious cardiac symptoms have developed.

Treatment.—Prophylaxis is of the greatest importance in syphilitic vascular disease. With regard to treatment, in the acute stages of syphilitic vascular disease it is generally thought that mercury is the best drug to use. Mercurial inunctions or soluble intramuscular mercurial injections should be given for 2 or 3 weeks before any intravenous injections are prescribed. Moreover, iodides should be given by the mouth, to absorb as far as possible the inflammatory products in the intima of the vessels. The indiscriminate use of arsphenamine and neoarsphenamine in the acute stages of syphilitic vascular disease has been followed by most disastrous results, their administration causing further swelling of the intima and further blocking and thrombosis of the small vessels. After mercury and iodides have been given for 3 or 4 weeks, neoarsphenamine, should be administered cautiously in small doses and gradually increased.

Thrombo-Angiitis Obliterans

This name was suggested by Buerger in 1908 for a disease characterised by acute inflammation of the deep arteries and veins, and sometimes by a migratory inflammation of the superficial veins in the extremities. Thrombosis develops and the vessels become occluded.

Ætiology.—The malady is found most commonly in middle-aged male Hebrews. The cause is unknown, but the pathological changes suggest that it is due to an infection. Syphilis is usually not present, the Wassermann reaction being negative. Excessive tobacco smoking has been suggested as a predisposing factor.

Pathology.—The deep vessels of the arms and legs, especially the latter, are occluded by thrombosis in various stages of organisation; their walls are traversed by vessels, and show a little inflammatory infiltration. In about a quarter of the cases this is associated with a migratory phlebitis in the superficial veins of the limbs. The condition is characterised by extensive progressive thrombosis, with organisation, with little inflammation of the vascular coats.

Symptoms.—The onset is gradual with pains in the feet and toes. The patient is unable to walk for more than a few minutes without severe cramp-like pain in the legs (intermittent claudication, see page 1041). The thrombi in the superficial veins, when they occur, are also very tender. Redness of the extremity, especially when in a dependent position, is often noted, while blanching occurs when the limb is raised. Diminution or loss of pulsation in the arteries, such as the radial or dorsalis pedis, is often present. In the later stages, the cramp-like pain becomes intense, and the disability in walking often leads to marked mental depression. Trophic changes appear in the skin, with gangrene, and fissures and ulcers may occur.

Diagnosis.—(1) Raynaud's disease more often attacks females; the upper extremities are most affected; and X-rays show marked atrophy of the bones of the hands. This is not present in Buerger's disease. (2) In erythromelalgia the limbs become red and flushed, but the arteries pulsate forcibly; gangrene does not occur. (3) In gangrene due to Mönckeberg's sclerosis, the calcified arteries may be well seen by means of the X-rays.

Prognosis.—The course of the disease varies. Some cases progress

rapidly, while others last for years. Gangrene may require high amputation of the limb.

Treatment.—As the cause is not known, there is no specific treatment. With regard to drugs, iodides and glyceryl trinitrate are used. Gentle massage is useful, and diathermy sometimes helps. Ultra-violet therapy has been tried. Buerger recommends *passive postural exercises*, and employs the following method: "The affected limb is elevated, with the patient lying in bed, to from 60 to 90 degrees above the horizontal, being allowed to rest upon a support for from thirty seconds to three minutes, the period of time being the minimum amount of time necessary to produce blanching or ischæmia. As soon as blanching is established, the patient allows the foot to hang down over the edge of the bed for from two to five minutes, until reactionary hyperæmia or rubor sets in, the total period of time being about one minute longer than that necessary to establish a good, red colour. The limb is then placed in the horizontal position for about three to five minutes, during which time an electric heating pad or a hot-water bag is applied, care being taken to prevent the occurrence of a burn. The placing of the limb in these three successive positions constitutes a cycle, the duration of which is usually from six to ten minutes. These cycles are repeated over a period of about one hour, some 6 to 7 cycles constituting a séance" (Leo Buerger, *The Circulatory Disturbances of the Extremities*). Others claim that the maintenance of a high venous pressure and stimulation of the heart are the most effective lines of treatment. Pain is relieved by rest in the recumbent position, and heat applied to the painful limb by electric pads or electric light baths is also useful. Ulcers of the legs should be treated surgically.

Polyarteritis Nodosa or Periarteritis Nodosa

Polyarteritis nodosa is a rare complaint characterised by prolonged fever and the occurrence of nodular swellings, and in some cases aneurysms of the medium-sized arteries. It may affect arteries in almost any part of the body, producing a very diverse symptomatology.

Ætiology.—Young adults are most commonly affected, and males more often than females. The cause is unknown. The Wassermann reaction is negative, but the pathological changes and course of the disease suggest an infectious agent.

Pathology.—The medium-sized arteries are usually affected, especially those of the heart, kidneys, and intestines. A remarkably focal acute inflammation extends through all the coats of the artery with hyaline or fibrinoid necrosis of the arterial wall, and within the lumen are often found thrombi, which may become organised. Aneurysmal dilatation is usually present. There may be many polymorphonuclear leucocytes and some mononuclear cells, lymphocytes, and plasma cells; eosinophil cells are a characteristic but inconstant finding. White or yellowish-white nodules, from the size of a pin's head to that of a pea, can be seen on the arteries. Owing to the alteration in the lumen of the vessels, necrosis and infarcts occur in the organs supplied.

Symptoms.—The disease may start in almost any way, even with bronchial catarrh or with epigastric pain. There is tachycardia and irregular fever, with marked prostration. Some cases may start as an acute illness, simulating nephritis or rheumatic carditis; in others long continued malaise is the main

presenting symptom. Acute abdominal pain may be caused by disease of the mesenteric arteries—indeed, even perforation of the intestine and peritonitis have followed. If the arteries of the heart are involved, evidence of myocardial disease will be present; and when the kidneys are affected, blood and casts appear in the urine. Occasionally bronchial asthma, cough and hæmoptysis have been noted. Later, in a small proportion of cases, nodular swellings, varying in size up to a pea, may be felt in the subcutaneous tissues of the abdomen, thorax, and limbs. Examination of blood shows the anæmia and a moderate leucocytosis. Blood cultures are sterile.

Diagnosis.—This is extremely difficult, owing to the variable symptoms displayed. In most cases, a pyrexial infection, of unknown origin, has its nature revealed only post-mortem. Rarely, however, where a node was felt in the subcutaneous tissues and excised during life, the diagnosis has been made before death. The diagnosis should now be made more often if it is suspected in any obscure and varied illness in which there is some evidence of arterial involvement.

Prognosis.—It has been said that in most cases death occurs within a few weeks to a few months after the onset of symptoms. Now, however, when more cases are recognised, it is found that many recover and that the disease may run an intermittent course for many years.

Treatment.—This is the same as that of any acute infection. Arsenic, mercury, and quinine should all be tried, though the results up to now have not been encouraging. In the main the treatment should be symptomatic as the parts involved are so varied.

DIFFUSE HYPERPLASTIC SCLEROSIS

The diffuse hyperplastic sclerosis of Jores and Evans, formerly known as arterio-capillary fibrosis of Gull and Sutton, is characterized by intimal hyperplasia, especially of the smaller arteries and arterioles, and hypertrophy of the media, particularly of the medium-sized arteries.

Ætiology.—Diffuse hyperplastic sclerosis is common in late middle age, and is by no means a senile change. In the great majority the causes are those of hyperpiesia (see p. 1065). The affection may also be due to gout and lead poisoning, and chronic nephritis. In rare cases associated with chronic interstitial nephritis, it may occur in young children. It is more common in males than in females. The inherited constitution is of great importance as shown by the high familial incidence in certain cases. Syphilis has no part in the causation of this condition, though, of course, it may be present in syphilitic cases.

Pathology.—The condition is widespread, frequently involving the whole arterial system. It affects the smaller arteries and the arterioles, and the medium-sized arteries. The kidneys and spleen are most commonly affected, especially the first; the next most frequently, the brain; while the pancreas, liver, suprarenal glands, stomach and intestines are less often implicated. The characteristic lesion consists of a cellular proliferation of the intimal cells and increase of hyaline material. At a later stage there is fatty degeneration in the arterioles alone. The thickening of the intima may lead to obliteration of the lumen of the vessels. There is hypertrophy of the media of the medium-sized arteries, *e.g.* the radials, with little or no

change in the intima. In the case of the smaller arteries and arterioles, a patchy ischæmic fibrosis of certain organs, *i.e.* the kidneys and brain, may take place. Hæmorrhages may also occur.

There may be co-existent atheroma, *e.g.* of the cerebral and coronary arteries, and, it may be, of the aorta, due to age or, in the opinion of some, the result of the hypertension.

Symptoms.—In diffuse hyperplastic sclerosis the vessel wall may be felt to be uniformly thickened—the so-called "whip-cord" artery. The degree of hardening of the arteries is found on palpation to vary at different times. The artery feels hardest when the vessel is most contracted and consequently smallest. As the muscular arteries are those chiefly affected, the radial, brachial, and temporal arteries are involved. The systolic blood-pressure in cases of simple hyperpiesia may be 160–240 mm. or more; it may reach even 300 mm. in cases associated with chronic interstitial nephritis. Symptoms of cardiac hypertrophy are common in the early stages, but in favourable cases they may not appear for years. In some cases cardiac hypertrophy is followed by dilatation, with its attendant symptoms. Headache, of a throbbing and bursting character, and generally in the occipital region, is an early symptom of arterial hypertrophy, and giddiness and fullness in the head are frequently complained of. Transient paralysis may occasionally be met with, and this has been attributed to spasm of the hypertrophied arteries. Later on, cerebral hæmorrhage may occur, with the production of hemiplegia. Albuminuria and casts in the urine may be found, while profuse renal hæmorrhage may occur. Uræmic symptoms do not occur frequently and then not till late unless the condition is secondary to chronic nephritis. Gastro-intestinal symptoms are often present. The patient may first complain of dyspepsia. A chronic diarrhœa without obvious cause in an elderly man should lead to a careful examination of the arteries and kidneys. Bronchitis and emphysema may mask a cardiovascular hypertrophy, and the enlargement of the heart may be overlooked unless there is a careful examination of the blood-pressure. The changes in the fundi are numerous and characteristic, and have been discussed in the section on hypertension (see pp. 1066, 1067). Intermittent claudication is not uncommon in these cases.

Prognosis.—The prognosis depends very largely on the degree of renal involvement. In hyperpiesia the condition may last for many years and only be terminated by hæmorrhage into the brain, the ischæmic fibrosis of the kidney, which accompanies it, being of no clinical importance. If, however, there is evidence that the cardiovascular hypertrophy and high blood-pressure are complicated by true nephritis, the condition is a grave one and uræmia may ensue; and when well-marked albuminuric retinitis is present death usually occurs within six months, though very rare cases have been recorded where a certain amount of ocular change has persisted for years.

Treatment.—The first indication is to remove the cause of the condition as far as possible. As a rule the most important thing is the regulation of the patient's life, the removal of anxiety and the reduction of his work and activity to a reasonable amount. The reduction of alcohol and tobacco is often needed, and it is the average daily consumption that counts in this direction. Any gouty tendencies should be corrected by the administration of alkalis and intestinal antiseptics, such as sodium benzoate. All sources of focal sepsis, whether in tonsils, teeth, nasal sinuses, or genito-urinary tract,

should be carefully sought for and, if found, removed. Moderation in food and drink, with regular exercise and care in promoting diaphoresis, is essential. Turkish and vapour baths may be given cautiously. The administration of a purgative pill once a week, and the use of a mild saline purgative each morning are indicated; while in acute crises the abstraction of one pint of blood from the arm has often saved life.

MÖNCKEBERG'S MEDIAL SCLEROSIS

This form of degeneration is accompanied by a deposition of lime salts in the middle coat.

Ætiology and Pathology.—The cause is undoubtedly a senile degeneration of the elastic tissue and the muscle of the large muscular arteries, and a deposition of masses of lime salts in the dying tissue. It has no relation to syphilis. This degeneration has been caused experimentally in animals by a great variety of toxins. In man the causation is obscure, but it is common in diabetes and in old people. The lime salt is deposited, more or less symmetrically, within the media in plaques, which encircle part or all of the lumen. The affection is very common in the arteries of the leg below the bifurcation of the femoral; occasionally the radial and ulnar arteries are affected; rarely the aorta.

Symptoms.—The symptoms are coldness and œdema of the legs, as the result of defective circulation through them, and finally, and not uncommonly, gangrene results, this form of degeneration being usually present in senile and diabetic cases. The arteries feel like pipe stems, and sometimes crackle when rolled beneath the finger. They can be well seen by means of the X-rays.

Prognosis.—This depends partly upon the amount of gangrene present and partly upon the associated conditions.

Treatment.—It is clear that if amputation has to be undertaken a local amputation is of little value, and the limb should be amputated above the knee, as the arterial degeneration almost aways extends to the bifurcation of the femoral artery.

FATTY DEGENERATION OF THE MEDIA

Fatty degeneration of the media occurs commonly in all arteries. *It tends to occur in cases of high blood pressure, and is consequently a common and important secondary complication of diffuse hyperplastic sclerosis.* It is probably the result of toxins or lack of nourishment, and is frequently present in cases of severe anæmia. It also occurs in old age, and is associated with cardiovascular hypertrophy. The muscle fibres become lost, being replaced by fibrous tissue. The vessel wall usually becomes weakened and is liable to rupture.

ATHEROMA

Synonyms.—Atherosclerosis; Degeneration of the Arterial Intima.

Definition.—Atheroma is a variety of arterial degeneration which affects

and is almost confined to the intima. It is characterised by the accumulation of debris, which is at first fatty and later becomes impregnated with lime salts. The Greek word was used by Galen to signify a swelling full of gruel-like material.

Ætiology.—There is no doubt that atheroma is found more frequently and is more widespread with advancing age. Long life is a question of the blood vessels, and it has been well said that a man is only as old as his arteries. The quality of the arterial tissue that has been inherited may be poor, and a tendency to the development of atheroma at about the same age is often seen in all the members of certain families, thus showing the influence of heredity in the production of the condition. Atheroma also results from the amount of wear and tear to which the vessels have been subjected. It appears as a secondary change in cardiovascular hypertrophy, so that it tends to be more frequent in patients with hypertension than in other subjects of the same age. The affection is much more common in men than in women, and in subjects who have hard and prolonged mental or physical work. Moreover, it is much more common in the aorta than in the pulmonary artery, and when it does occur here it is nearly always associated with high pulmonary pressure, *e.g.* in mitral stenosis and in pulmonary fibrosis. The severity of the disease increases with the length of time during which the high blood-pressure has existed. Over-eating and stress and strain of modern life are probably factors in the ætiology of the condition. It has been said that the most important cause of atheroma is chronic poisoning. Acute degeneration of the media has been found after typhoid fever in young people, and has been caused experimentally by the injection of bacterial toxins. Chronic lead poisoning and gout are also ætiological factors. On the other hand, syphilis has no connection with atheroma, though the condition of the aorta known as syphilitic mesaortitis was for a long time confused with the chronic intimal degeneration we now know as atheroma. Disease of the kidneys probably has no direct relation with atheroma, though the high blood-pressure of chronic interstitial renal fibrosis and of secondary contracted kidney is an important factor in producing atheroma in the large elastic arteries.

Pathology.—Atheroma occurs in the large elastic and muscular arteries. The condition is usually most marked in the aorta. The coronary, cerebral, retinal, radial, brachial, and temporal arteries are frequently affected. The peripheral arteries may be normal to the feel in cases where there is advanced atheroma of the coronary or cerebral arteries. In the slighter degrees, minute yellow flecks or patches on the aorta may be observed by the naked eye. In the later stages, yellow plaques or buttons are conspicuous, and under the microscope masses of large fatty crystals, with a covering layer of fibrous tissue, are to be noted. Atheromatous plaques may ulcerate and the contents be discharged into the aorta, and thrombi are often deposited on the surface of these atheromatous ulcers. As the atheroma may be associated with degeneration of the media, a general dilatation of the aorta is very common. On the other hand, circumscribed aneurysm due to severe medial degeneration very rarely occurs. The aortic valves are frequently affected by atheromatous degeneration, and aortic stenosis or aortic regurgitation may result. A yellow atheromatous patch is commonly seen on the anterior flap of the mitral valve. Atheroma often causes great narrowing of the

lumen of the vessels, and eventually a thrombosis may form and complete occlusion result; this is the most dangerous result of atheroma; it frequently occurs in the large divisions of the coronary arteries, especially in the anterior interventricular branch of the left, and is not uncommon in the vessels of the brain. With regard to the heart, atheroma has a most profound influence, owing to the fact that it is one of the commonest causes of fibrosis of the myocardium; but the chief danger is a sudden blockage of one of the coronary arteries, generally the anterior ventricular branch of the left coronary. In these cases, if death does not follow immediately, a sudden softening of the heart muscle (myomalacia cordis) may occur, and an aneurysm of the heart may result, and in certain rare cases actual rupture of the heart wall has followed—a broken heart. In the brain, atheroma results in cerebral thrombosis, and is the commonest cause of this condition in old people, and in middle-aged people who have not had syphilis. Very commonly, however, especially in those cases of atheroma where the blood-pressure is raised, hæmorrhage may occur. In most cases of atheroma the kidneys are not involved, though occasionally atheromatous plaques may be found on the branches of the renal artery. Should, however, one of these plaques be large enough to cause much narrowing of an interlobar artery, a wedge-shaped red area of fibrosis in the distribution of the artery will occur. The renal changes, however, are relatively unimportant, and they rarely lead to symptoms during life.

Symptoms.—The blood pressure is only raised if the atheroma happens to complicate cardiovascular hypertrophy. In the aorta a diffuse dilatation, with pulsation in the supra-manubrial notch, may be present. The radial, brachial, and temporal arteries are often irregularly thickened and tortuous and can often be seen pulsating beneath the skin, but this dilatation has none of the important effects that so often follow a saccular aneurysm. Atheroma of the coronary arteries frequently gives rise to cardiac failure, and more often to angina pectoris; and sudden death is not uncommon, owing to a sudden thrombosis of a large branch. In the brain, hemiplegia usually results from hæmorrhage and more rarely from thrombosis. Ocular symptoms are rare in atheroma of the retinal arteries, which may be seen with the ophthalmoscope to be irregularly swollen and tortuous, but swelling of the optic disc and retinitis are not present.

Prognosis.—The course and prognosis are extremely uncertain. Circulation through the diseased vessels may proceed fairly satisfactorily for a long time, but thrombosis may occur with alarming suddenness, and with the direst results, if a cerebral or cardiac artery is affected.

Treatment.—The treatment of atheroma is unsatisfactory. Prophylaxis exists in the removal of the cause when possible. Great attention should be paid to diet, and repletion should be studiously avoided. Alcohol and tobacco should be taken with greatest moderation, and attention should be paid to regular exercise, and the action of the skin should be assisted by warm baths. It is doubtful if drugs are of value in the treatment of atheroma; but small doses of potassium iodide seem to be of some use in absorbing the degenerative products and assisting in the circulation of the blood through the obstructed areas.

OTHER DEGENERATIONS ALLIED TO ATHEROMA

There are closely allied intimal degenerations, in which this accumulation of fatty debris is absent.

In *fibrotic degeneration*, muscle fibres and to a less extent elastic fibres disappear after little or no fatty degeneration, and the intima becomes fibrotic. This may be found in any artery, but is very common in the smaller arteries, for instance, the interlobular and afferent arteries of the kidneys, where atheroma is very rare.

Hyaline degeneration affects the ultimate arterioles in the kidney and other organs; the muscle and elastic fibres disappear rapidly, and the intima becomes swollen and hyaline, and usually fatty. It is common with high blood pressure, but is otherwise rare.

Both these forms of intimal degeneration are of importance, because intimal fibrosis is much less focal than atheroma, and both forms, in affecting arteries of small calibre, lead in the same way as atheroma to a narrowing of the lumen sufficient to cause ischæmic destruction of the tissues. They may therefore be considered together with atheroma in their clinical effects.

ARTERIAL INFILTRATION

The commonest form of infiltration is amyloid infiltration.

Ætiology.—Amyloid or lardaceous disease occurs in cases of long suppuration due to pyogenic organisms, and is frequently associated with the secondary pyogenic infections that occur in tuberculosis of the bones and joints, in chronic syphilitic ulceration, and in actinomycosis.

Pathology.—The amyloid substance is extracellular and is deposited beneath the endothelium of capillaries, the reticulum of adenoid tissue and the pulp of the spleen, and in the smaller arteries and veins, especially in their middle coats. The affected organs are firm to the touch and have a waxy appearance. The amyloid substance can be demonstrated macroscopically by pouring tincture of iodine on the affected organ, the waxy material being stained a deep mahogany colour. Microscopically, an iodine staining may be used, or a methyl-violet stain, which colours the amyloid substance pink and the parenchymatous cells blue. In the kidney, the small arterioles in the glomeruli, those around the convoluted tubules and those in the medulla, are first attacked. In the intestine, the arterioles in the villi stand out clearly. There are two forms of amyloid infiltration of the spleen: the diffuse waxy spleen, where the venous sinuses are outlined and the central artery of the Malpighian capsule is affected; and the sago spleen, where the Malpighian capsule is greatly enlarged by the amyloid infiltration—its central artery is untouched, but its branches into the capsule are greatly swollen by the waxy material. In all these organs the parenchymatous cells are unaffected directly by the amyloid infiltration, but in the later stages necrose, owing to interference with their nourishment.

Symptoms.—The patient is pale, but often has a waxy complexion with a bright colour in the cheeks. Chronic, profuse and painless diarrhœa is common. The urine contains a large quantity of albumin, and is usually fair in

amount and of low specific gravity. The liver and spleen are enlarged, and ascites and œdema of the legs are often present.

Prognosis.—If the chronic suppuration can be cured, the condition may sometimes disappear; but in the majority of cases this is not possible, as the septic condition is engrafted on to a chronic tuberculous or other granulomatous condition, which is almost always impossible to eradicate.

Treatment.—This consists in trying to remove the cause.

INTERMITTENT CLAUDICATION

So far the various conditions discussed have been classified according to the underlying pathology. Intermittent claudication is only a symptom, but it provides such a characteristic syndrome that it is best taken separately here. The term " intermittent limp " or claudication is applied to a condition in which severe pain, in one or both legs, comes on after walking for a certain distance.

Ætiology and Pathology.—In the large majority of cases this syndrome occurs in elderly men, who have well-marked calcification of the middle coat of the arteries of the lower limbs (Mönckeberg's degeneration, *q.v.*). In rarer cases it may be present in atheroma or diffuse hyperplastic sclerosis or thrombo-angiitis obliterans (*q.v.*). It may be associated with high blood pressure, gout, diabetes, syphilis, or excessive indulgence in tobacco.

The symptoms are due to the arteries of the leg being unable to supply the muscles with the increased flow of blood that the limb requires during walking. It is one of the earliest signs of partial impairment of the arterial flow.

Symptoms.—The characteristic pain comes on after walking a certain distance and is brought on more quickly by faster walking. It may be accompanied by cramp in the calves, and also by numbness or tingling sensations. It causes the patient to limp and finally to stop. After resting for a minute or two, he is able to continue walking, but the symptoms again recur after he has walked for a further period. Sometimes the pain may only be described as tiredness or may only be felt in the feet and unless a careful examination is made the pain may be attributed to flat feet. Often the patient may suffer from angina pectoris, the causation of the two conditions being very similar, or his anginal pain may seem to disappear as his intermittent claudication appears, really because he is no longer able to walk quickly enough to provoke the anginal pain. In nearly all cases of long standing there is absence of pulsation in the dorsalis pedis artery, or in the posterior tibial of the affected limb, which often shows signs of circulatory disturbance, being swollen, congested, and mottled, while the toes may be white and cold; but in early cases the arteries may still carry enough blood when the patient is resting so that it is more difficult to confirm the diagnosis. The amount of calcification in the arteries, which is often very extensive, may be determined by X-ray examination. In many cases dry gangrene of the limb has supervened.

Prognosis.—The prognosis is bad, but the attacks may persist for years before more serious results, such as gangrene, appear.

Treatment.—Exercise must be limited, and the patient warned to move

slowly and avoid hurrying in his walks. The production of intermittent venous occlusion may give helpful results. Diathermy has been used to relieve the pain. Heart muscle extracts and preparations of the pancreas given hypodermically have been tried, but without much success. Dry gangrene may require amputation of the limb, and when threatened may be relieved by removing the sympathetic nerves round the femoral artery.

ANEURYSM

Definition.—The word aneurysm is derived from the Greek to widen or dilate, and may be said to include any dilatation of an artery.

Aneurysms are generally divided into—

1. TRUE ANEURYSMS, in which the walls of the dilatation are formed by the coats of the artery. These may again be divided into—

(*a*) *Diffuse aneurysm.*—These are general dilatations of an artery. The dilatation is generally not great, and is of little clinical significance except that it indicates medial degeneration. The artery is sometimes tortuous in addition. The so-called cirsoid aneurysm is a very extreme example of this.

(*b*) *Circumscribed aneurysm.*—These are limited to a segment of an artery or to a part of its circumference.

(*c*) *Dissecting aneurysm.*—These are caused by the splitting of the coats of the artery, the blood having passed through the lumen into the wall of the artery, separating one coat from another.

(*d*) *Arterio-venous aneurysm.*—In these there is a communication between an artery and a vein; there are two varieties in this group—(1) aneurysmal varix, and (2) varicose aneurysm.

2. FALSE ANEURYSMS are those following a wound or rupture of an artery, with the formation of a diffuse or circumscribed hæmatoma, and are bounded by tissues external to the wall of the artery.

When a true aneurysm ruptures and gives rise to a false aneurysm the resulting structure is known as a mixed aneurysm.

Ætiology and Pathology.—The two main factors in the causation of aneurysm are—(1) loss of the muscular and elastic fibres in the wall of the artery; (2) strain. The latter is generally brought about by repeated and prolonged muscular effort, and high arterial pressure may sometimes be an additional factor. The importance of strain as a causal factor is borne out by the fact that aneurysm is much more frequent in men than women—about five to one—and occurs more frequently in the fourth decade of life than at any other period. It also occurs much more frequently in hard manual workers, such as dock labourers, soldiers and sailors. *By far the most common cause producing weakening of the large elastic arteries is syphilitic inflammation. In persons dying of aneurysm, examination of the aorta in the neighbourhood of the aneurysm will generally reveal mesaortitis* (see page 1031). In the first part of the aorta this is nearly always so, but as one gets farther away from the aortic valves an increasing number of aneurysms are due to atheroma and non-syphilitic degeneration of the media; in the abdominal aorta less than half are syphilitic. Small aneurysms may also result from erosion of the walls of the arteries in cases of septic endocarditis—the so-called mycotic aneurysm. Frequently these are multiple; they occur most often

in the cerebral arteries or in the peripheral arteries. Extensive growth of streptococci and septic granulations may be seen in the neighbourhood of the dilatations.

Aneurysm may also be the result of congenital defects in the media of the vessel, which is very commonly seen about the circle of Willis, at the junction of the anterior communicating artery with the anterior cerebral. The aneurysms vary from about the size of a pin's head to that of a pea, and not infrequently their rupture gives rise to a diffuse subarachnoid hæmorrhage, the origin of which is often overlooked unless careful search is made for the aneurysm. Congenital aneurysm has also been described in the aorta, at the point of insertion of the ductus Botalli, and in cases of coarctation of the aorta, in which condition there is great narrowing of the aorta just below the origin of the left subclavian artery.

Loss of support by surrounding tissues also appears to lead to the production of aneurysm, *e.g.* at the base of a gastric ulcer a small aneurysm often projects as a nodule and is liable to rupture. Peptic erosion may also be a cause of weakening the walls of such arteries. In the cavities of the lungs, occurring as the result of pulmonary tuberculosis, it is quite common to find an aneurysm on the walls of the arteries lying in such cavities.

It is very doubtful if external trauma alone is ever the cause of true aneurysm, but injury to the artery by penetrating wounds by knives or bullets may certainly cause it.

Slight medial degeneration leads to diffuse aneurysm, and severe medial degeneration may cause circumscribed aneurysm. It is the usual cause of circumscribed aneurysms of muscular arteries, such as the popliteal, but is a very rare cause of circumscribed aneurysm of the aorta. Atheroma itself does not lead to aneurysm, but it may be complicated by medial degeneration. Continued high blood-pressure is an important contributory factor in the formation of a diffuse dilatation of the aorta, but this has few clinical resemblances to saccular or even to fusiform aneurysm.

One of the most striking appearances in an aneurysm is the coagulation of blood in the sac itself. This does not occur in diffuse dilatation of the aorta, but in those cases of sacculated aneurysm where the wall has become roughened. The sac becomes lined with fibrinous deposits, and occasionally an aneurysm may be cured by the deposition of successive layers of fibrin, so that the sac becomes almost completely filled. On the other hand, thrombus in aneurysms may form emboli and so lead to infarcts. Again, in many fatal cases of aneurysm, rupture and hæmorrhage have taken place, the deposition of fibrin having failed to prevent the blood reaching the surface. Rupture may take place externally, or into any of the hollow viscera or the serous cavities. Rupture into the pleura is common, as also is rupture into the trachea or into the œsophagus. In these cases, death is usually sudden, though oozing may have taken place some time before the final rupture. When the hæmorrhage forces itself into the connective tissues or muscles, it takes place much more slowly, and in the cases of the limbs may allow time for treatment. An aneurysm often exercises pressure on the other organs and structures in its neighbourhood. The heart is displaced away from the aneurysm, and the blood vessels are often narrowed so that circulation through them is impeded. The trachea, the bronchus, the œsophagus, and the nerves passing near the aneurysm also suffer. When the aneurysm meets

bony tissues, absorption of the bone takes place and the vertebræ are frequently eroded in this way, the bone being absorbed more rapidly than the intervertebral cartilage. When the aneurysm presses against the anterior surface of the chest, the ribs and sternum are pushed forward and finally are absorbed and perforated.

I. ANEURYSM OF THE THORACIC AORTA AND ITS BRANCHES

These are two types—(1) The diffuse aneurysm, or general dilatation, which occurs in medial degeneration of the aorta ; and (2) the circumscribed, usually saccular, aneurysm, almost always the result of syphilitic inflammation.

General Dilatation of the Aorta (Diffuse Aneurysm)

Symptoms.—In general dilatation of the aorta the enlargement is extensive, but never reaches a very great size. The symptoms are generally due to atheroma and the medial degeneration that accompanies it. Very often there is interference with the coronary circulation, and this leads to diminution of the circulation of blood through the heart and consequently to cardiac pain. The aorta may sometimes be felt pulsating in the supra-manubrial notch, and the X-ray photograph will show general dilatation of the aortic arch. When the aortic ring is not stretched, the dilatation of the aorta beyond it may lead to the formation of a systolic murmur. Occasionally these patients die suddenly, on account of thrombosis of an atheromatous branch of a coronary artery. Provided there is no aortic regurgitation or coexisting coronary disease, patients with a dilated aorta may live for many years without serious discomfort.

Circumscribed Aneurysm

These are generally saccular but may be fusiform.

Symptoms.—Aneurysm of the Ascending Part of the Arch of the Aorta.—An aneurysm of the ascending part of the arch tends to grow forward and outwards, and to produce a pulsating tumour that is palpable and audible at the level of the second or third interspace ; hence it is often called the *aneurysm of physical signs*. It often erodes the ribs and sternum. The tumour is tender and is often the seat of pain, which may be constant but is increased by exertion. A soft systolic murmur may be heard over it. If syphilitic aortitis spreads to the aortic valve or if the part adjacent to the aortic valves is affected, the aortic ring may be dilated and aortic regurgitation will take place. There will then be hypertrophy and dilatation of the left ventricle, with an aortic diastolic murmur, and the symptoms of aortic regurgitation will be added.

The pressure effects produced by an aneurysm of the ascending aorta are as follows : The heart is displaced downwards and to the left. The superior vena cava is pressed upon ; this may result in cyanosis of the head and neck, and œdema of the arms, and enlarged veins may occasionally be seen coursing over the front of the thorax. Very rarely the aneurysm may rupture into the superior vena cava, in which case the symptoms noted may come on quite suddenly and are very marked. There is often a systolic thrill, and on auscultation a continuous murmur, which is increased during

systole, is of great diagnostic value. The aneurysm may press upon the right bronchus, causing a chronic cough, due to irritation of the bronchus and stasis of its contents, and deficient or absent breath sounds over the upper lobe of the right lung. It may occasionally press upon the pulmonary artery and in rare cases, actually open into it, causing great dilatation of the right ventricle and auricle. Such aneurysms may present themselves to the left of the sternum rather than in the usual place, the right. Aneurysm of the ascending aorta has been known to perforate into the right ventricle and much more frequently into the pericardial sac. When the aneurysm comes forward it may irritate the pleura; and in some cases a loud pleuritic rub, audible over the aortic area, may be one of the early signs. Not uncommonly this form may rupture into the pleura or sometimes externally.

ANEURYSM OF THE TRANSVERSE ARCH OF THE AORTA.—As the arch of the aorta passes from right to left it also passes from before backwards, and consequently aneurysms arising from the transverse and descending parts of the aortic arch are situated more deeply in the chest than those arising from the ascending portion. Aneurysms of the transverse and descending parts of the aortic arch have been called by Broadbent *aneurysms of symptoms*, because their presence has often to be inferred by the pressure symptoms that they produce, while a pulsating tumour is only present in the very late stages and may not appear at all.

1. *Pain.*—Pain is one of the commonest and earliest symptoms of aneurysm. It may often occur behind the sternum or across the back and pass down the left arm and be very severe: it then lasts longer than true anginal pain and is more liable to occur at night; this form of pain occurs when the ascending aorta is distended. When, however, the transverse arch is affected the pain is sometimes felt on the left side of the neck and even in the occipital region; it is probable that this pain in the neck is a reflected pain caused by abnormal afferent impulses reaching the cervical spinal cord as a result of the distension of the transverse arch. A boring, persistent pain in the chest is probably the result of direct pressure of the aneurysm. Sometimes there may be true angina pectoris owing to involvement of the mouths of the coronary arteries.

2. *Respiratory Symptoms.*—Dyspnœa is common in aneurysm, and apart from associated heart disease is usually caused by pressure upon a bronchus. There is often stridor, which in this case is heard both in inspiration and in expiration. Hæmorrhage also occurs as a result of leaking of an aneurysm through the bronchus. It may at first be slight, but often a huge gush of blood supervenes, causing death. It is said that reflex irritation of the vagi will occasionally cause bilateral adductor spasm of the vocal cords and marked dyspnœa. In this case the stridor is only heard with inspiration and disappears if a little chloroform is inhaled. Patients with aneurysm often have a ringing, rough, brassy cough. If the pressure on the bronchus has been gradual, secondary changes occur in the lung, and compression of the left bronchus in the early stages may produce over-distension of the left lung with diminished or absent breath sounds, so as to lead to a suspicion of pneumo-thorax; later on bronchitis occurs with dilatation of the bronchus with expectoration of purulent phlegm. Pressure on the trachea may occasionally be observed in cases of aneurysm of the aortic arch, the larynx being drawn downwards and backwards with each cardiac pulsation. A

physical sign described by Surgeon-Major Oliver is known as *tracheal tugging*. The patient should be placed in the erect position, and directed to close his mouth and elevate his chin. The cricoid cartilage should be grasped between the finger and thumb and gentle steady upward pressure be made upon it. If there is an aneurysm, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand. This sign may occur in aneurysm before other symptoms are evident, but is not very reliable.

3. *Pressure on nerves.*—(*a*) The left recurrent laryngeal nerve.—This nerve courses round the arch of the aorta and passes up behind it, and is consequently often involved in aneurysm of the transverse arch. The abductor fibres of the recurrent laryngeal nerves succumb to the effect of pressure before the abductor fibres and consequently the vocal cord is at first in the position of adduction. During respiration, the right vocal cord moves up to and meets the adducted left vocal cord and respiration is unaffected. During phonation, the right vocal cord again comes up to and meets the left vocal cord, and the voice may be quite normal. It is therefore clear that a laryngoscopical examination may reveal the early stage of pressure on the left vocal cord before there has been any alteration in the voice. As the pressure increases, the adductor muscles are affected and the left vocal cord remains motionless in the cadaveric position half-way between full inspiration and full expiration. The voice is now hoarse, and it not uncommonly happens that hoarseness is the first symptom for which the patient presents himself. (*b*) The sympathetic nerve.—Pressure upon the sympathetic nerve causes first of all irritation and later on a paralysis of the cervical sympathetic fibres. When the sympathetic is irritated, the pupil on the same side is dilated, and there may be sweating and flushing of the same side of the face and ear. When the cervical sympathetic is paralysed, the pupil is smaller than on the opposite side, the eyeball may be sunken into the orbit, and there may be a slight degree of ptosis. Unequal pupils in aneurysm are, however, frequently found without any of the other symptoms of sympathetic irritation or paralysis, and in these cases Doctors Wall and Walker suggest that the difference in the pupils is due to the pressure of the aneurysm upon the arteries passing to the neck. They have shown that in a condition of low blood pressure the pupils are dilated, whilst in a condition of high blood pressure they are contracted, and that pressure upon one common carotid will cause dilatation of the pupil on the same side. They point out that under these conditions the dilated pupil is constantly on the same side as the smaller temporal pulse, and they consider that the dilated pupil and the small pulse are due to the same cause, namely, pressure upon the arteries supplying that side of the neck. Unequal pupils also occur as the result of syphilitic disease of the nervous system. We may get bilateral pin-point pupils, or the pupils may be unequal and irregular in outline. In both cases the reaction to light is lost, while the reaction to accommodation remains. (*c*) Pressure upon the intercostal nerves occasionally results from an aneurysm that presses backwards and erodes the vertebræ and posterior portions of the ribs. In these cases the pain is very severe along the affected nerves. In the distribution of the nerve itself the skin may be anæsthetic—the so-called *anæsthesia dolorosa*. (*d*) In some cases the aneurysm presses upon the brachial plexus, shooting pain occurring in the head and neck and down the right arm.

4. *Pressure upon the branches springing from the aorta.*—This is not uncommon, and may result in the absence of one radial or temporal pulse, or inequality between the two pulses. If the innominate artery is pressed upon, the right radial and temporal arteries may be small and imperceptible, while in an aneurysm of the transverse arch of the aorta, the left subclavian artery is compressed, in which case the left radial pulse may be affected. A sphygmographic tracing is often of value in demonstrating the difference between the two pulses, and a forced expiration, by increasing the intrathoracic pressure, will often accentuate the difference between the two sides. When the pulses are markedly unequal, the blood-pressure is also diminished on the side of the feebler pulse; a difference of pressure of over 30 mm. between the two sides is in favour of aneurysm provided it is not due to coarctation of the aorta.

5. *Pressure on the œsophagus.*—This may result in slight difficulty in swallowing but the dysphagia is very rarely important. Occasionally the aneurysm may ulcerate into the œsophagus so that death takes place from a sudden rupture.

Aneurysm of the Descending Portion of the Arch.—In these cases the sac frequently projects backwards and erodes the vertebræ from the third to sixth thoracic, causing great pain and occasionally compression of the spinal cord, resulting in paraplegia. Dysphagia is more common, and sometimes a tumour appears in the region between the scapula and the spine, and may attain a very large size.

Aneurysm of the Descending Thoracic Aorta may occur close to the diaphragm. Aneurysm of this form is frequently overlooked, pain in the back being the most prominent early symptom.

Diagnosis.—*Inspection.*—This is most essential. Abnormal pulsation should be looked for in the thorax, and can often be seen when the patient is seen obliquely in a good light. Posterior pulsation is generally observed to the left of the spine. Enlarged veins over the chest, suffusion of the face, and alteration in the pupil may be noted. The apex-beat is often displaced from its normal position, especially when the sac is large, this being due to pressure of the aneurysm on the thorax; the heart itself is seldom hypertrophied, unless there is a leakage through the aortic valves.

Palpation.—Palpation may reveal the area and degree of the abnormal pulsation. There may only be a diffuse impulse, but if the sac has perforated the chest wall, a forcible heaving and expansile impulse may be felt. Occasionally a diastolic shock is to be noted. This has been thought by some to be due to the forcible closure of the aortic valves producing an effect within the aneurysmal sac; another explanation is that the contraction of the heart draws in the ribs during systole at the point where they are adherent to the aneurysm and the diastolic shock is produced by the elastic recoil of the ribs and costal cartilages. Occasionally a systolic thrill may be felt.

Percussion.—A dull area may in some cases be made out in the second right interspace in cases of aneurysm of the ascending aorta. Much more rarely an aneurysm of the arch may press forwards and to the left, and produce dullness below the left clavicle. Pressure upon a bronchus may at one period result in hyper-resonance from lung distension, and later, owing to absorption of air in the lung, the percussion note may become dull.

Auscultation.—There may be no murmur, even in a large aneurysm, but a systolic murmur is not uncommon. When both systolic and diastolic murmurs are heard, aortic regurgitation is present in addition to the aneurysm. Accentuation of the aortic second sound is a most constant auscultatory sign of aneurysm, but it occurs with syphilitic aortitis before an aneurysm has developed.

Reference has already been made to alteration in the radial and temporal pulses. Exceptionally, in a large aneurysm of the descending aorta there may be absence of pulsation in the abdominal aorta and peripheral arteries of the legs, the dilatation of the thoracic aorta being sufficient to convert the intermittent into a continuous stream.

Examination by radioscopy is most important in every case where aneurysm is suspected and may give valuable information. The chest should be examined from the anterior, the posterior and the right oblique positions. The pulsation of the tumour and its relation to the aorta may actually be seen, but photographs should always be taken, both in the anterior-posterior and oblique positions, as much information is obtained from the density of the shadow cast by the aneurysm. If the latter is very dense, it can be reasonably inferred that deposition of the laminated clot has taken place within the sac.

Complications and Sequelæ.—The main complication causing death is rupture, which may take place either externally, into the pericardium, into the pleura, into the œsophagus, into the bronchus, or into the lung tissue itself. Pressure on the trachea, causing stridor and respiratory obstruction, is a very distressing complication. Bronchitis may occur during the course of the illness, and may be recovered from more than once. Broncho-pneumonia and gangrene of the lung not infrequently occur when there is pressure upon a bronchus, and empyema may occasionally result. Tuberculosis of the lung may coexist with aneurysm, but death from hæmoptysis, the result of perforation of a deep-seated aneurysm into the bronchus, has often been mistaken for the profuse hæmorrhage of tuberculosis. Cardiac failure is responsible for a large number of deaths. This may be the result of interference with the circulation through the coronary arteries, and in other cases it is due to the aortic regurgitation. Cerebral embolism sometimes occurs in cases of aortic aneurysm, a portion of the clot within the artery becoming displaced and passed up to the brain.

Course.—Most cases live from 2 to 5 years from the time when the first symptoms have appeared. Occasionally life may be prolonged for several years by treatment, provided the diagnosis is made early. Spontaneous cure may be obtained by deposition of laminated clots within the cavity of the aneurysm, but this is comparatively rare.

Diagnosis.—Intrathoracic aneurysm is sometimes difficult to diagnose from intrathoracic neoplasm. In both there may be an externally projecting tumour, but in aneurysm the pulsation may be seen to be expansile. The diastolic shock indicates an aneurysm. Systolic murmurs may occur in both conditions, but the ringing aortic second sound is of great importance, and is rarely heard in tumours. Tracheal tugging is in favour of aneurysm, while progressive wasting and enlargement of glands in the neck are in favour of neoplasm. Aneurysm, as a rule, occurs in apparently healthy men between 45 and 60 years of age, whereas malignant growth in the chest is associated

with emaciation and pallor. In aneurysm there is a greater likelihood of the pupils and pulses being unequal, while in neoplasm œdema of the upper extremities and chest wall is not uncommon. In all cases an X-ray examination should be made, and will nearly always clear up the diagnosis. Clinical evidence of infection by syphilis and a positive Wassermann reaction are obviously important.

A violently pulsating thoracic aorta, either in association with aortic regurgitation or with violent throbbing of the heart, may lead to the unfounded suspicion of an aneurysm.

In cases where an empyema is pointing on the left side in the region of the heart, the tumour may pulsate. The throbbing is usually diffuse and widespread, and there is a coexistence of a pleural effusion. Exploration with a fine needle will usually settle the diagnosis. It must, however, be remembered that occasionally an empyema may be the result of extension of septic trouble from a bronchus which has become compressed by an aneurysm.

Prognosis.—In aneurysm this is always difficult. Complete cure is very unlikely, although pain and other unpleasant symptoms and physical signs may give way to treatment. The presence of aortic regurgitation is unfavourable, while an aneurysm progresses much more slowly in people of a placid disposition and those who lead a quiet life. Even in cases where treatment has apparently been most successful and pain and dyspnœa have been apparently relieved, sudden death from rupture may occur.

Treatment.—The recognition that the main cause of aneurysm is the weakening of the wall by syphilitic mesaortitis has brought anti-syphilitic remedies into the forefront of modern treatment of aneurysm of the thoracic aorta. Mercurial inunctions and injections have been but little tried, but in many cases a good deal of benefit has been observed. The iodides have been given in aneurysm for many years—long before syphilis had been recognised as a cause of the condition. The most striking effect of iodide is the relief of pain, and this may be obtained by even small doses, such as 5 grains three times a day. In all cases, however, large doses, such as 20 grains three times a day, should be given a trial. Neoarsphenamine has been given intravenously in many cases with great success; it should always be tried when the diagnosis is made early enough, but should never be used if congestive failure or paroxysmal nocturnal dyspnœa have developed.

Efforts to produce clotting within the sac should be tried in early cases of aneurysm. Tufnell's method—that of a complete rest and restricted diet—is only of historic interest. The patient had to lie in a quiet and secluded room for several months. Few patients put up with such a rigid diet and rest. Secondly, the administration of lime-salts, such as the chloride or lactate of calcium, should also be tried, in an endeavour to promote clotting within the sac. The gelatin treatment has been abandoned.

Many patients with intrathoracic aneurysm do better if, after a preliminary rest with the treatment appropriate to their stage, they are allowed to follow their general vocations, provided their work be not too strenuous for body or mind. Nearly always it will be necessary for their activity to be curtailed. Patients should be cautioned to take things as easily as possible, to avoid alcohol, to eat with great moderation, and to avoid any sudden exertion. At least 10 hours should be spent in bed. A certain amount of tobacco may be smoked.

Special symptoms may have to be treated. For severe pain, cyanosis and dyspnœa, venesection will often give marked relief. Amyl nitrite and iodide of potassium are of great service in relieving the anginal pain of aneurysm. Severe paroxysmal dyspnœa is nearly always due to direct pressure on the trachea; both inspiratory and expiratory stridor are present. The inhalation of chloroform does not give relief, and tracheotomy is useless. In some very rare cases there may be a bilateral abductor spasm of the vocal cords, due to irritation of the vagi, and relief may be obtained by chloroform. Intubation of the larynx is preferable to tracheotomy, which should never be performed to relieve the dyspnœa of aneurysm.

Surgical Treatment.—This may be considered under four heads—(1) ligature of the vessels arising from the arch of the aorta; (2) the passage of wire into the sac with or without galvanism: (3) needling the sac; and (4) ligature of the neck of the sac. There are few cases where the outlook under medical treatment is so bad that the certain risks and uncertain benefits of surgical treatment can be advised with wisdom.

Ligature of vessels has been of little service in the case of aneurysm of the aorta. In aneurysm of the innominate artery, combined simultaneous ligature of the right common carotid and subclavian arteries may be tried, but even this may be insufficient to prevent the flow of blood through the sac. Moore's method of introducing silver or zinc wire into the sac through a cannula has been used, but the best results have been in cases of abdominal rather than intrathoracic aneurysm. Puncture of the aneurysm and scratching its wall with the point of a needle, as advocated by Sir William M'Ewen, has sometimes been partially successful. Ligature of the neck of the sac may be undertaken when it appears to be small, but suitable cases are very rare.

Aneurysm of the Innominate Artery.—This is not uncommon. It forms a pulsating tumour, which can sometimes be felt above the right clavicle, and nearly always produces marked diminution in the right radial and temporal arteries. In this form of aneurysm, paralysis of the right recurrent laryngeal nerve occurs not infrequently, the right vocal cord being paralysed instead of the left.

Aneurysm of the Carotid and Subclavian Arteries is mainly of surgical interest. It has been thought to be most frequent in the common carotid, especially in women, but in many of these cases there is really a kinked carotid artery, due to hypertension and athero-sclerosis, that simulates an aneurysm. Subclavian aneurysm is nearly as frequent as carotid aneurysm. Syphilis is found in nearly all cases near the aorta but trauma becomes more important towards the periphery.

II. ANEURYSM OF THE ABDOMINAL AORTA AND ITS BRANCHES

Aneurysm may occur in any part of the abdominal aorta, but it is much less common than aneurysm of the thoracic aorta. A forcible dynamic pulsation of the vessel is often mistaken for aneurysm and no case should be diagnosed as aneurysm unless a tumour can be grasped between the fingers. Often in true aneurysm there is evidence of syphilis and the Wassermann reaction is positive. A systolic thrill can sometimes be felt, and a systolic murmur is, as a rule, audible. The complications in abdominal aneurysm are

many. Death may result from complete obliteration of the lumen by clots, or by erosion of the vertebræ and compression of the spinal cord, resulting in paraplegia. Occasionally the superior mesenteric artery may become blocked by a clot and acute intestinal obstruction result. The commonest complication is rupture, which generally takes place into the retro-peritoneal tissues, with the formation of a large rapidly-growing tumour in the flank. More rarely death takes place from rupture into the peritoneum or duodenum.

Treatment.—The treatment of abdominal aneurysm is the same as that of thoracic aneurysm. In cases where medical treatment is unsuccessful after a fair trial, surgical measures should be undertaken and are more likely to be successful than in thoracic aneurysm.

ANEURYSM OF THE SPLENIC ARTERY is very rare. A tumour can be felt near the spleen and it may perforate into the colon. If the diagnosis can be made, removal of the aneurysm and of the spleen should be undertaken.

ANEURYSM OF THE MESENTERIC ARTERY, which is also rare, generally results in plugging of the vessel or its branches, with the result that acute intestinal obstruction takes place and death occurs from this cause.

ANEURYSM OF THE HEPATIC ARTERY is very rare.

ANEURYSM OF THE RENAL ARTERY has occasionally been noted, and in some cases successfully removed.

ANEURYSM OF THE BRACHIAL ARTERY used to be common, but is now rarely seen.

ANEURYSM OF THE FEMORAL ARTERY is much more common, and is most often traumatic.

ANEURYSM OF THE POPLITEAL ARTERY is one of the most common of the peripheral aneurysms. It has been suggested that this is due to the fact of the exposure to stress and strain to which the popliteal region is subjected during violent lifting efforts.

In all cases of peripheral aneurysm not due to trauma, a syphilitic basis should be invesigated; but the aneurysms of the muscular arteries of medium size are almost invariably due to medial degeneration, and a syphilitic aneurysm would be most unusual. The treatment is mainly surgical. Distal or peripheral ligature and excision have all been tried, and more recently Matas has suggested treatment by *Reconstructive Endoaneurysmorrhaphy*. After rendering the limb exsanguine, he freely opens the arterial sac and by a process of suturing reconstructs a channel between the afferent and efferent artery of the sac. This is theoretically the best treatment, but in practice it is often found impossible.

When the symptoms warrant surgical treatment, proximal ligature is probably the method most frequently used for a large artery and excision of the sac for a smaller one. Proximal ligature as close to the aneurysm as possible has been the classical operation since the time of John Hunter. It should be combined with distal ligature, as this does not increase the risk of gangrene and diminishes the risk of spreading infection or of an embolus becoming detached.

Until the War of 1914–1918 great care was taken to avoid injury to the vein, but it was found that proximal and distal ligature of the vein as well as of the artery reduced the risk of gangrene. This should therefore be the routine surgical treatment.

III. DISSECTING ANEURYSM

This may originate in an atheromatous ulcer. Very often the dissection of the coat is small, especially when the blood-pressure is not high. When, however, there is a very high blood-pressure and much degeneration of the media, an extensive dissecting aneurysm may occur. The degeneration of the media may cause a small split in the intima and the dissection separates the intima from the media, so that in some cases there may be a double tube instead of a single aorta. Extensive dissection frequently causes sudden death, but in other cases the patient may live on, and the association of a rapidly beating heart and a feeble pulse in the lower limbs has been suggested as a clinical sign by which the condition may be recognised. The immediate picture is very similar to that of a coronary thrombosis. If the dissection spreads up the common carotids, symptoms from interference with the cerebral circulation may follow and this soon after an attack, suggesting coronary thrombosis may reveal the diagnosis. Occasionally the patient makes a complete recovery and lives for years with the circulation through the new channel made by the dissection.

In many cases of extensive dissecting aneurysm of the aorta, due to medial degeneration, vascular hypertrophy is well marked, and consequently the blood pressure was high during life. Less commonly dilatation, rupture and the dissecting aneurysm of the aorta are apparently due to congenital weakness, histological evidence of degeneration or inflammation being absent.

IV. CIRSOID ANEURYSM

Cirsoid aneurysm is a condition in which an artery is dilated and tortuous. Occasionally it is due to medial degeneration of muscular arteries, particularly the splenic and temporal, but this form is of little clinical importance. More often it is due to defective development of the walls of arteries and their branches, and this form has been called serpentine angioma. The arteries, their branches, the capillaries, and even the efferent veins dilate progressively, causing destruction of the intervening soft tissues and erosion of bone. The superficial temporal, posterior auricular, and occipital arteries are most commonly affected. It also occurs in the brain, pancreas, orbit, and limbs. It is most common between puberty and 30 years of age. Although the condition is generally congenital it may develop greatly after some local injury such as a blow.

Pathology.—The arteries are dilated, thinned and very tortuous, and the disease tends to spread towards the capillaries and also along the arteries that feed the aneurysm. The skin over the aneurysm is often atrophied and may become ulcerated, leading to very dangerous hæmorrhage.

Symptoms.—There is an ill-defined pulsating tumour on the scalp, in which the tortuous vessels may be felt. In rare cases the tumour may be slow in its growth, but this is generally rapid and the skin over it ulcerates, leading to hæmorrhage.

Treatment.—This is very difficult. In limited cases the tumour may be excised. Generally, however, ligature of the peripheral arteries of the growth is more satisfactory. Electrolysis and injections of perchloride of iron into the

mass have been tried, with some success. Occasionally spontaneous cure follows some infection.

V. ARTERIO-VENOUS ANEURYSM

Arterio-venous aneurysms, in which an artery and a vein communicate, are of two kinds: (1) aneurysmal varix, where the two vessels anastomose directly; and (2) varicose aneurysm, where the sac separates the connecting vessels.

(1) ANEURYSMAL VARIX.—The aneurysm is usually traumatic in origin and used to be frequent at the elbow, as the result of venesection. The artery is wounded at the same time as the vein and they become connected, the result being that the vein becomes markedly dilated and tortuous.

The varix forms a soft, compressible, ill-defined tumour, which pulsates. Pain in the tumour is not uncommon. A marked thrill can often be felt and a loud briut may be heard over the tumour. If the limb is raised the tumour shrinks, while it becomes large and congested if the limb is held downwards. The limb below the tumour is often œdematous.

In some cases the aneurysm remains stationary, and all that is required is an elastic support. If, however, it tends to increase in size, the artery should be ligatured above and below its communication with the vein, and the vein should also be ligatured.

An intrathoracic aneurysm may become adherent to a vein and perforate into it. The most common site is when an aneurysm of the ascending arch of the aorta perforates the superior vena cava, but even this is rare. The latter vessel becomes greatly distended and an arterio-venous aneurysm is formed. There is often a sudden onset when the lumen of the two vessels becomes connected; there is congestion of the head and neck and upper limbs, great distension of the veins, and often œdema. On auscultation over the tumour, a continuous humming murmur is heard, with marked accentuation during systole.

(2) VARICOSE ANEURYSM.—This occurs when an artery and vein are simultaneously wounded. A false aneurysmal sac is formed in the tissues and communicates both with the artery and vein. The symptoms are similar to those of an aneurysmal varix, but in addition there is a pulsating tumour, which can be distinguished from the dilated vein. This form of aneurysm should be excised by open operation combined with four-fold ligature of the artery and of the vein. It is not often seen in civil life but is fairly common in war-time, mainly as a result of gun-shot wounds.

ARTERIO-VENOUS ANEURYSM OF THE ORBIT OR PULSATING EXOPHTHALMOS.—This is a form of aneurysm by anastomosis, due to a communication having formed between the cavernous sinus and internal carotid artery as it passes through it. It is generally the result of a fracture of the base of the skull. It is usually unilateral, but may be bilateral, and the communication may take place immediately after the fracture, or evidence of the lesion may only appear days or weeks after the injury.

The main symptom is protrusion of the eyeball, the globe being displaced outwards and downwards. It may be seen to be visibly pulsating, but if not, slight pressure upon the globe of the eye will bring out pulsation. A loud bruit, either continuous or increased during systole, may be heard anywhere

over the head ; this roaring sound is generally very distressing to the patient. There is great dilatation of the veins around the eyelids, conjunctivæ, and fundus. Headache is common

The condition may last for years, and in a few cases spontaneous recovery has taken place.

The treatment is either compression or ligature of the carotid artery. The great danger in ligaturing the carotid artery is the occurrence of cerebral softening and hemiplegia. To avoid this, it is better to ligature the artery temporarily and see if any cerebral symptoms tend to develop ; if they do, the ligature should be removed after 24 hours ; but if they do not, the ligature may be tightened and the artery completely occluded.

DISEASES OF THE PULMONARY ARTERIES

The pulmonary artery is much less frequently the seat of disease than is the aorta, but it is liable to be affected by pathological changes of a similar character to those that are found in the systemic arteries.

Ætiology and Pathology.—Four main pathological changes are generally recognised, namely.

1. HYPERTROPHY.—This condition is associated with an increase in the blood pressure in the lesser circulation and is found in cases of disease of the lungs, such as emphysema, pulmonary fibrosis, and bronchiectasis, and also in disease of the heart, such as mitral stenosis. The intima of the pulmonary arteries hypertrophies and is prone to degeneration, so that patches of fatty change (atheroma) appear in the hypertrophied tissue. This form of intimal degeneration is superimposed upon hypertrophy, which is the result of obstruction to the lesser circulation and is independent of inflammatory change.

2. INFLAMMATION.—There is no doubt that *syphilitic* inflammation may attack the pulmonary arteries as well as the aorta. The larger trunks may be affected by mesarteritis, and saccular aneurysms of the main branches have been described, but are rare. The smaller arteries and arterioles in the lungs may also be affected by syphilitic arteritis, with endarteritis obliterans. The endarteritis, either by itself or in combination with thrombosis, may lead to complete occlusion of the lumen. Ayerza and his pupils have emphasised the importance of syphilis as an ætiological factor in the production of cyanosis and congestive heart failure in the absence of the usual causes of these conditions, such as emphysema and fibrosis of the lungs, or mitral stenosis. Fatty or calcareous changes may occur as secondary changes in the walls of the inflamed arteries.

Tuberculous inflammation of the branches of the pulmonary arteries is also common. Tuberculous endarteritis obliterans is frequent in phthisis. Tuberculosis of the lung or a bronchial gland may extend through the wall of a large artery to its intima, giving an intimal tubercle which when softened can lead to a general dissemination. The wall of a pulmonary artery exposed in a tuberculous cavity is frequently weakened by tuberculous or pyogenic invasion from without, and an aneurysm results. The profuse hæmoptysis found in the latter stages of chronic pulmonary tuberculosis results from the rupture of one of these aneurysms.

3. Degeneration.—Degeneration of the intima secondary to intimal hypertrophy or to inflammation has been described above. Slight primary intimal degeneration, or atheroma, is not uncommon in elderly subjects. C. F. Coombs and others have described cases of a severe atheroma of the pulmonary artery in young subjects, in whom there was no evidence of syphilis or of pulmonary or cardiac lesions, and suggest that in these cases there is an inherited tendency to intimal degeneration.

4. Congenital Malformations.—In the majority of cases a pulmonary stenosis is present, but in rare instances dilatation of the vessel has been found. These conditions are described under congenital heart disease (*q.v.* p. 968).

Symptoms.—The symptoms of disease of the pulmonary artery are those of obstruction of the lesser circulation.

Dyspnœa is often an early symptom, and may occur on exertion or in nocturnal paroxysms. In the later stages it becomes constant, with attacks of orthopnœa. Cyanosis is one of the most characteristic manifestations, but it varies in intensity and also in the stage of the disease at which it appears. Cyanosis is due to an imperfect oxygenation of the blood passing through the lungs at each cardiac cycle. It will, therefore, be most marked in those cases in which only a small proportion of the blood passes through the lungs at each beat, as in congenital pulmonary stenosis, or those in which the capillary area in the lungs has been so reduced by emphysema or the lung itself has been so damaged by fibrosis that the circulating blood is imperfectly oxygenated. In mitral stenosis the degree of cyanosis is remarkably variable and probably depends as to whether secondary changes in the lungs have developed. In Ayerza's disease (syphilitic inflammation of the pulmonary arteries) the cyanosis may be extreme and the patients may have almost a black appearance (cardiacos negros). This may be due to the endarteritis obliterans of branches of the pulmonary artery, or to a coexisting syphilitic obliterating bronchitis, or a syphilitic pneumonia causing fibrosis of the lung.

Hæmoptysis may occur before cyanosis has become established or in the later stages. It may be slight or profuse, and may be associated with attacks of pulmonary artery thrombosis. Cough, with mucopurulent expectoration, is common, and attacks of vertigo may occur. Somnolence is not infrequently found when marked cyanosis is present. The fingers are not clubbed, except in cases resulting from bronchiectasis or fibroid lung.

The pulse is usually regular and the heart is much enlarged, especially the right ventricle. If mitral stenosis is present diastolic murmurs may be heard at the apex. There are no constant physical signs in the lungs, but if emphysema, fibrosis, or bronchiectasis has been the determining factor, the physical signs characteristic of these conditions will be found. Œdema is often present and may be extreme and the liver enlarged. The spleen is not palpable. The blood shows an increase in the number of red cells, up to 8,000,000, the number varying with the degree of cyanosis.

The radioscopic findings are characteristic. The right ventricle is enlarged, the pulmonary artery often dilated, and the branches of the pulmonary artery show more clearly than usual and can be followed into the lung and in some cases can be seen to pulsate. The electrocardiogram shows a marked right ventricular preponderance and alterations in the *P* wave, suggesting right auricular hypertrophy.

Diagnosis.—Cases of pulmonary artery affections secondary to pulmonary or cardiac disease can be distinguished by the presence of the symptoms and signs of the underlying lesion. There is no sure method of diagnosis between syphilitic and non-syphilitic cases. In syphilitic pulmonary arteritis the patients are usually between 30 and 50 years of age and may give a history of syphilitic infection. The Wassermann reaction in the blood is positive.

Course.—There may be a history of pulmonary symptoms, such as cough and dyspnœa, for many years. Later the intense cyanosis may develop, and this may last for 4 or 5 years. Some of these patients die in their sleep, but in others myocardial failure, with advanced anasarca, is the cause of death. Others die of complications, such as broncho-pneumonia.

Prognosis and Treatment.—The outlook depends on the causative factor. In early cases in which syphilis has been established as the cause of the inflammation of the pulmonary artery, anti-syphilitic treatment will retard the progress of the disease. In paroxysms of cyanosis, venesection gives marked relief. The usual treatment for congestive heart failure must be adopted, when this has supervened.

PHLEBITIS

Phlebitis or inflammation of the veins may be sharply divided into two great classes—(1) non-suppurative or plastic, and (2) suppurative. The terms endo- and peri-phlebitis have been used to indicate inflammation of the internal and external coats. Peri-phlebitis results from invasion of the veins by inflammatory processes outside it, or from injury. It may extend inwards towards the lumen of the vein, and result in endophlebitis and generally clotting of the blood within the vein. Endophlebitis is usually the result of poisons or microbes circulating within the vein. Inflammatory changes of a plastic type occur in the endothelium, and in consequence a clot or thrombus is set up within the vein. The clot may adhere to the vessel wall and completely obliterate it. Organisation of the clot by fibrous tissue may occur, the vein being transformed into a hard fibrous cord. In other cases the clot may become softened and broken down, and the circulation may be resumed through the vein. In certain cases changes in the composition of the blood may lead to clotting in a vein, and the presence of this clot itself may give rise to a plastic phlebitis; this is sometimes called *thrombo-phlebitis*. In other cases the vein and contained clot may become invaded by pyogenic organisms, and leucocytes will enter the clot and cause it to break down into a purulent fluid.

Plastic Phlebitis

Ætiology.—(1) Traumatic phlebitis; (2) the formation of a non-infective clot—thrombo-phlebitis; (3) gouty phlebitis may accompany an attack of gouty arthritis or may occur independently; (4) typhoid fever not infrequently causes phlebitis and thrombosis; (5) in pneumonia and influenza phlebitis is not an uncommon complication; (6) post-operative phlebitis is not at all uncommon in cases of operation on the lower abdomen and the

bladder; and (7) puerperal phlebitis or phlegmasia alba dolens frequently follows parturition.

Phlebitis may attack any vein, but is most common in the lower limb, particularly in the saphena vein.

Symptoms.—Phlebitis is accompanied by pain and tenderness in the course of the affected vein, which can be felt as a hard cord. The skin may become reddened over the superficial veins, and the limb is often œdematous when thrombosis has taken place. There is usually more or less febrile disturbance. In gouty phlebitis, the pain is often severe, the areas of inflammation are often multiple; there is a great tendency for more than one vein to be attacked at once, and, in opposition to most forms of phlebitis, the disease may be symmetrical.

Complications and Sequelæ.—The complications and sequelæ of plastic phlebitis are those of the thrombosis that accompanies it, and will be described under thrombosis.

Prognosis.—This is generally good apart from the risk of embolism or of the thrombosis spreading towards the large veins, such as superior or inferior vena cava. Treatment must be carefully carried out to minimize the risk of this.

Treatment.—Patients with phlebitis should be put to bed, and the limbs elevated and wrapped in cotton wool. All sudden movement, friction, or handling should be avoided. The bowels should be freely opened, as chronic constipation and stasis in the colon may impede the circulation in the iliac veins. In gouty phlebitis, the diet should be restricted to fish and light farinaceous foods, but when patients are marasmic and anæmic, the diet should be as liberal as their digestive powers will permit. In all cases of phlebitis foods containing much lime-salts, such as milk, should be limited. Potassium or sodium citrate with carbonate of ammonia and liquor ammonii acetatis are of service. Glycerin of belladonna smeared over the inflamed vein appears to ease the pain.

Suppurative Phlebitis

Ætiology.—Suppurative phlebitis is the result of infection of the walls of the veins with pyogenic organisms. The micrococci may be in the circulating blood, as in some cases of puerperal phlebitis, or they may reach the veins from a focus of suppuration around it, as in facial carbuncle, middle-ear disease, or inflammation of the portal veins—suppurative pylephlebitis.

Pathology.—The coats of the vein are infiltrated with leucocytes, the clot which has formed within the vessel breaks down into yellow pus, and abscesses are not infrequently found along the course of the vein. Not uncommonly the septic inflammation spreads along a vein, splitting up the coats.

Symptoms.—There is a throbbing, smarting pain in the region of the affected vein, and the part drained by it is œdematous. Not infrequently the septic process spreads along a vessel. There is often fever, a rapid pulse, a dry tongue, and delirium, and in many cases a succession of rigors indicates the development of pyæmia.

Complications and Sequelæ.—These depend upon the situation of the vein and the occurrence of emboli, owing to breaking away of the softened

clot. (See Thrombosis.) When the vein is superficial the diagnosis is easy, but when a deeply-seated small vein is affected the only symptoms may be those of the pyæmia to which it gives rise.

Treatment.—The prevention of this disease by asepsis is one of the great advances in modern surgery. As soon as the disease is recognised, a ligature should be placed upon the vein between the affected area and the heart, the inflamed vein should be thoroughly laid open, the septic clot removed and the cavity thoroughly cleansed. In some cases where numerous abscesses are formed, amputation is the only means of arresting the general infection.

Thrombosis of the portal vein is commonly the result of septic conditions within the abdomen, most often suppuration in the region of the appendix. The condition is not always acute. Peptic ulcers may lead to portal thrombosis, and tubercular glands along the course of the portal vein have been found to cause clotting within the lumen of the vessel. Dysenteric ulcers resulting from bacillary dysentery may also give rise to septic portal thrombosis, but typhoid ulceration very rarely does so.

The effect of portal thrombosis is to produce a portal pyæmia, portions of the clot passing into the liver and causing abscesses within the radicles of that organ. Occasionally the portal vein itself becomes converted into a sac containing pus, and the liver is then riddled with abscesses along the course of the portal branches. This condition is known as *portal pylephlebitis*.

Symptoms.—The symptoms of septic portal thrombosis are the occurrence of fever and of rigors. The liver becomes enlarged and tender, and jaundice of a slight degree is quite common.

As the condition is such a generalised one, recovery very seldom takes place, even if treatment is adopted.

Treatment.—This consists in removing the cause and incising any liver abscesses.

MAURICE CAMPBELL.

THROMBOSIS AND EMBOLISM

Thrombosis is the name applied to the coagulation of blood within living vessels, whether in the heart, the veins or the arteries.

Embolism is the process whereby a portion of clot or other substance, such as parasites, fat globules, masses of bacteria or particles of tumour, is carried from one part of the circulation to another, and is impacted when it arrives at a vessel too narrow for its further progress. An infarct is the degenerated or necrosed condition of the tissues due to interference with the circulation of blood within it, and can be caused by embolism, thrombosis, endarteritis, endophlebitis or strangulation of veins. An infarct is generally wedge-shaped in outline, with the base towards the periphery of the organ affected. As seen post mortem, it is either yellowish-white in colour (the white infarct), or blood-red in colour (the hæmorrhagic infarct).

In the case of the white infarct the tissue deprived of its blood supply becomes permeated with lymph from the surrounding living tissue, and coagulative changes take place in it. In the case of the kidney or spleen, the

coagulable material is sufficient to render the infarct hard. In the case of the brain, less coagulable lymph is poured out, and the area of the brain affected becomes softened. In the early stages there is often a zone of congested vessels around a white infarct; this is a reaction on the part of the surrounding living tissues to the presence of the dead material. Later the infarct becomes invaded by fibrous tissue and a scar results.

In hæmorrhagic infarct, coagulation and necrosis also take place, but to this is added hæmorrhage, by diapedesis of the red blood cells from vessels of the collateral circulation. A hæmorrhagic infarct is commonly seen in the lung; a cone-shaped area of lung tissue becomes hard and dark-red in colour. Should the embolus, instead of being aseptic, contain living micro-organisms, a septic process is set up within the infarct and an abscess results. Such purulent abscesses are commonly seen in the lungs, as the result of septic phlebitis, and occasionally in the systemic system, as the result of septic endocarditis.

THROMBOSIS

Ætiology.—The causes of thrombosis are—(1) altered conditions of the blood or increase in its coagulability; (2) slowing of the current of the blood within the vessels; and (3) a lesion of the lining membranes of the vessel or cavity of the heart. Thus, thrombosis may occur in cases of anæmia or after infections or operations, where the blood is more coagulable than normal; in the appendages of the dilated auricles of the heart where the movement of blood is feeble or in peripheral vessels or in the lungs when the circulation as a whole is feeble, *e.g.* with a failing heart; and it may result from inflammation of the lining of the vessel or degenerative changes in its endothelium, especially when there is atheroma associated with much narrowing of the channel obstructing the circulation.

(1) Intra-Cardiac Thrombosis.—This is one of the commonest forms of thrombosis and is very important. It occurs in the left auricle, when it has become extremely dilated as the result of mitral stenosis. The ante-mortem clot generally begins to form in the dilated appendix of the left auricle, but may extend by the deposition of excessive layers of fibrin to invade the auricle itself so that a large ball thrombosis be formed within the cavity. Portions of the ante-mortem clot may break away from the thrombus, and may be carried into the left ventricle and into the general circulation, and embolism may occur in the brain, spleen, kidneys, intestines and the main arteries of the limbs. This danger is mainly to be feared in the first few weeks after the deposition of the thrombus, but may of course recur as fresh thrombi form.

Ante-mortem clot is occasionally deposited among the meshes and cavities of the dilated left ventricle. In cases of cardiac fibrosis and myelomalacia cordis, the result of disease of the coronary arteries, and especially after coronary thrombosis and cardiac infarction, the lining of the heart may become affected and fibrinous deposits occur within either ventricle. Lastly, in septic endocarditis, large vegetations, consisting of clot and masses of micro-organisms, may occur. Inflammation of the ventricle and of the auricle may also be present, and ante-mortem clot may be deposited on these roughened surfaces. Portions of this clot may leave the ventricle and pass into the

general arterial circulation, where the effect produced will depend upon whether the emboli are aseptic or contain micro-organisms.

Thrombosis in the right auricle occurs in many conditions where there is gradual cardiac failure and dilatation of the right side of the heart. Portions of ante-mortem clot form in the right auricular appendix, and parts may break away and pass into the lungs and an embolism of the pulmonary artery result. If the embolus is sufficiently large to cause blocking of the artery or of one of its main branches, sudden death ensues, but if only one of the smaller branches is affected, a pulmonary infarct results. Much more rarely ulcerative endocarditis occurs on the right side of the heart, and portions of the valves or affected clot reach the lungs in the same way.

(2) ARTERIAL THROMBOSIS.—Arterial thrombosis is rarer than venous thrombosis. It is sometimes due to arterial embolism, but is also the result of trauma or disease of the arterial walls, such as atheroma or endarteritis.

Thrombosis of the coronary arteries is a very important condition, since it is a frequent cause of sudden death and of serious cardiac disability. It has already been described (pp. 991–994). The usual artery affected is the anterior interventricular branch of the coronary artery. Atheromatous plaques are constantly found within the thrombosed vessel, and sometimes atheroma has occluded the orifice of the artery. In cases where the circulation has been slowed and greatly diminished before the final clotting, changes in the wall of the left ventricle are very common. Syphilitic mesaortitis sometimes occludes the orifices of the coronary arteries but this is much less common.

Thrombosis is very frequent in the small cerebral arteries, especially when they have become narrowed as the result of disease. In early middle-age this narrowing is usually the result of syphilitic endarteritis, but most patients are older and then the arterial lumen is diminished by atheromatous changes in the wall of the vessel.

Thrombosis of the main artery of a limb usually results in gangrene; the limb becomes first white and pallid, later mottled in appearance, and finally black. If the patient survives the immediate shock and the disease to which the thrombus owes its origin, a line of demarcation will form between the vital and devitalised tissues, and the limb should be amputated well above this level.

Thrombosis of the retinal artery is more common than embolism. There is a sudden painless loss of sight in one eye, and generally the blindness is permanent and complete. Within a short time there is opacity of the central parts of the retina, and the macula shows up by contrast as a bright cherry-red spot.

(3) VENOUS THROMBOSIS.—*Thrombosis of the lateral sinus* occurs in disease of the middle ear. The mastoid cells become infected with pyogenic organisms and the disease spreads to the petrosal or sigmoid sinus. The clot in the vein becomes softened by pyogenic organisms, and particles break away and are conveyed to the lungs, in which pyogenic abscesses are formed.

The symptoms of septic thrombosis of the lateral sinus—and its continuation of the jugular vein—are infiltration of the tissues of the neck, with a cord-like induration of the vein itself, with some restriction of the movements of the head. There is a history of a chronic and often offensive discharge from the ear of the same side. A high temperature and rigors,

due to flooding of the circulation by poison, occur when a portion of the septic clot is dislodged. In these circumstances the jugular vein should at once be ligatured below the clot, in order to prevent further portions of the clot gaining access to the blood stream. A radical mastoid operation should also be performed, the sinus opened and its septic contents removed.

Thrombosis of the longitudinal sinus of the brain occurs as the result of injuries and infected wounds of the skull. It is a common war injury, the vertex of the head having been injured by a bullet as the soldier passes along the trench. Thrombosis of the cranial sinuses also occurs in marasmic patients, but it is usually agonal.

In many of these cases, owing to the vertical position of the leg areas in the brain, a paraplegia is produced, while the arms are not affected. The condition should be treated by trephining and draining the cranial cavity. Occasionally the longitudinal sinus becomes thrombosed in septic conditions in children and also in chlorotic anæmia in adults.

Thrombosis of the cavernous sinus is not infrequently the result of the extension of a chronic suppurative process of the sphenoidal cells at the back of the nose. The cavernous sinus is also affected by septic processes on the face; a small boil on the nose or a mosquito sting on the face may produce a septic thrombosis of the angular vein; this vein communicates with the ophthalmic vein, and the septic clot may extend along the latter into the cavernous sinus. As the venous plexuses of the pterygoid and zygomatic fossæ communicate through the foramina in the middle fossa and by the inferior ophthalmic vein, purulent inflammation of the jaw and of the teeth sockets is sometimes a cause of cavernous thrombosis. The result is that a marked degree of exophthalmos and swelling of the lids, and œdema of the optic disc and extensive retinal hæmorrhages occur. Not infrequently the septic condition of one cavernous sinus spreads to that on the other side through the circular sinus, and the exophthalmos may be double. Death from pyæmia or meningitis results. Owing to the position of the sinus, operation is impossible.

Thrombosis of the central retinal vein is common in elderly patients with athero-sclerosis and high blood pressure. The loss of sight is not so sudden or complete as in blockage of the artery. There is often albuminuria. Glaucoma often develops, but if the thrombosis is in a tributary vein the degree of recovery may sometimes be fairly good.

Femoral thrombosis is perhaps the commonest form of thrombosis. It frequently occurs after parturition and in anæmic and marasmic states. It is met with after infectious fevers, especially after typhoid fever, more rarely after influenza and pneumonia. It also follows operations, especially if a septic condition has been dealt with, or results from the operation. The thrombosis generally occurs in the femoral vein, and there is often some rise of temperature and a slight rise in pulse rate. It is most common on the left, because of the pressure of the right common iliac artery on the left common iliac vein. The limb affected becomes œdematous and a hard cord is found in the course of the vein.

In other cases thrombosis of the veins may also occur in marasmic conditions secondary to carcinoma, tuberculosis and tertiary syphilis.

Complications and Sequelæ.—Collateral circulation is usually satisfactorily accomplished in femoral thrombosis. In cases where the arteries

as well as the veins are involved gangrene may occur. Occasionally the thrombosis may spread up into the iliac vein and into the inferior vena cava, in which case both legs may become swollen and œdematous. Even in cases where the inferior vena cava has become thrombosed, recovery may take place, collateral circulation being established by means of veins passing up from the legs into the axillæ. If, however, the clot reaches the entrance to the renal veins, death nearly always results from renal thrombosis. Embolism is not at all uncommon in femoral thrombosis, the clot passing into the right auricle, and then into the right ventricle and pulmonary artery.

Treatment.—Complete rest for at least 3 weeks, as a precaution against embolism, should be insisted upon. Limitation of foods containing quantities of lime salts, such as milk, and the administration of citrates and salts of ammonia will materially help in the treatment of the case. The leg should be elevated and wrapped in cotton wool and kept warm.

EMBOLISM

Embolism may occur in three main situations, namely—(1) in the systemic circulation; (2) in the pulmonary circulation; and (3) in the portal circulation.

Emboli in the systemic circulation are derived from ante-mortem clots in the left auricle and left ventricle. These clots are formed in cases of mitral stenosis and more rarely in mitral regurgitation, and also when the left ventricle is greatly dilated and hypertrophied. In these cases the emboli are aseptic. Systemic emboli also occur in septic endocarditis, when portions of the valve break away or masses of fibrin and micro-organisms pass into the general circulation. These emboli are septic, and when they reach their destination usually form abscesses.

Emboli in the pulmonary circulation may have their origin in clots formed within the right auricle and right ventricle, or more rarely from septic endocarditis of the tricuspid and pulmonary valves; they may also come from any part of the systemic venous system. A very important form of pulmonary embolism is met with after abdominal operations and after childbirth. About the tenth day after an apparently successful abdominal operation or an uneventful parturition, a pulmonary embolism may occur with appalling suddenness. Death may take place at once, or hæmoptysis and pleurisy supervene. The clot forms in the common iliac vein, at the junction of the internal and external iliacs. Not only may a clot pass along the veins, but we also get droplets of fat in fat embolism, air bubbles in air embolism, and masses of parasites in parasitic embolism.

Two recent studies, one of autopsy cases of hæmorrhagic infarct of the lung and one of post-operative cases of thrombosis and embolism, support the view that embolism is much the most common cause of pulmonary infarction (87 per cent.) and that this generally comes from a venous thrombosis. In 14 per cent. of the autopsy cases a massive pulmonary embolism was the main diagnosis and most of these were after operations or fractures. In 47 per cent. heart disease with the accompanying stagnation of the blood stream appeared to be a predisposing factor. A potential source for the

embolus was found in 75 per cent., most often in the pelvic or leg veins. Massive embolism was more likely to occur on the tenth day but was not infrequent at any time in the first fifteen days; it was independent of sepsis and depended on the stagnation of the blood stream, either from the state of the heart or more often from the mechanical conditions of rest. Smaller infarcts were more closely associated with sepsis (which suggests that the embolism is more often due to the breaking off of a small part of the thrombus) and more erratic in the time of their appearance.

In embolism in the portal circulation portions of clot in the radicles of the portal vein are finally arrested in the liver.

Symptoms.—1. Embolism of the Cerebral Arteries.—The onset is sudden, and the left side of the brain is rather more often affected than the right. Hemiplegia or aphasia is produced; consciousness is lost only for a few minutes during the attacks.

2. Embolism of the Splenic Artery.—The onset is sudden, with pain in the left side and sudden enlargement of the spleen, which is very tender. During the next few days, the spleen diminishes in size, but it often remains permanently enlarged.

3. Embolism of the Renal Arteries.—Sudden pain in the back is produced, and blood and a little albumin are present in the urine. The hæmaturia may last for a day or two, or longer if a larger branch was involved.

4. Embolism of the Superior Mesenteric Artery.—The patient is seized with sudden, violent abdominal pain and distension. The collateral circulation, in spite of the numerous vascular arteries that supply the intestine, fails, and gangrene of the small intestine results. There is a complete intestinal obstruction, and blood finds its way into the stools and into the peritoneal cavity. Operation should be undertaken at once, but owing to the large amount of bowel affected recovery is very rare.

5. Embolism of the Central Artery of the Retina.—This is not an uncommon event in cases of mitral stenosis and in septic endocarditis of the aortic and mitral valves. The patient is seized with pain in the eye and becomes suddenly blind on one side. The optic disk becomes pale and the retinal vessels small. Occasionally only a single branch of the vessel is affected. The same picture is found more often as a result of arterial thrombosis in elderly patients with athero-sclerosis or high blood pressure.

6. Embolism of a Large Artery in a Limb.—This sometimes occurs. There is acute pain in the limb, followed by numbness and loss of power. The pulse is imperceptible below the seat of the embolism, and gangrene results.

7. Air Embolism.—Air may enter the veins during operation on a large vein, or during intravenous injection of saline or other solutions, or after distension of the bladder and the urethra with air. Air embolism is undoubtedly capable of causing death, but a small quantity may enter a vein without any effect whatever, or, if some disturbance should arise, without fatal termination. The exact way in which air embolism causes death is doubtful; it may be due to arrest of the pulmonary circulation or to cerebral anæmia.

The diagnosis is not difficult; the respiratory embarrassment, convulsions, the feeble pulse and the characteristic sound upon air entry into the veins are usually sufficient.

Treatment consists in immediately occluding the vein into which the air has entered. Stimulants should be administered hypodermically and nitrite of amyl inhaled. Venesection may be used to relieve the embarrassment of the heart.

8. Fat Embolism.—Fat may reach the blood vessels in cases of fracture of bones and in cases of hæmorrhage into or rupture of the liver. The fracture is usually situated in the long bones, generally in the tibia or femur, and occasionally in the ribs. Fat embolism may occur within a few hours of fracture of the bones.

The fat droplets first lodge in the capillaries of the lungs. Occasionally they are forced on through the lungs into the general circulation, and the glomeruli of the kidney may be plugged with fat cells, and they may also lodge in the brain or spinal cord.

The patient becomes cyanosed, and crepitations from œdema of the lungs may be heard at the bases. The temperature remains normal. Cerebral complications, such as delirium, coma and rarely localised paralysis, may be found. The urine should always be examined, as oil drops have been detected by staining with osmic acid, and also the retinæ, as in one case the fat drops were recognised in the retinal vessels before death.

When fat embolism occurs within a few hours of fracture of the bones, it has to be diagnosed from the general shock of the accident. It is doubtful whether fat embolism in the lungs can alone cause death; more probably this is due to the disturbance of the kidneys or lesions of the brain.

The indication for treatment is to sustain the heart. Nitrite of amyl is often useful, and inhalations of oxygen should be given to lessen cyanosis.

9. Paradoxical Embolism.—In certain cases of venous thrombosis, emboli occur not only in the lungs but also in the systemic arteries. It has been shown that in these cases the embolus has passed from the right auricle to the left auricle through a patent foramen ovale. These crossed or paradoxical emboli are often preceded by pulmonary embolism, which causes a rise in pressure in the right auricle and a fall in the left auricle, so that the embolus can pass from the right to the left side of the heart.

Maurice Campbell.

ARTERIAL BLOOD PRESSURE

HYPERTENSION

In hypertension the systolic and diastolic blood pressure readings are persistently—not necessarily permanently—above certain levels, from whatever cause. Authorities differ somewhat as regards these levels, for the limits of normal variation are fairly wide, and, moreover, it is now practically universally believed that the blood pressure does not normally increase with advancing age as much as was previously thought to be the case; but it is generally agreed that persistent readings above 150 and 90, or at any rate 160 and 90, in adult males, and 170 and 100 in the elderly are pathological.

It is important to note that a transient increase in the blood pressure

readings, especially of the systolic, may occur with nervous excitement, such as is not infrequently incidental to a medical examination.

The late Sir Clifford Allbutt introduced the term *hyperpiesia* to denote a clinical condition in which there is a persistently raised blood pressure independent of renal disease. Some writers use the term *essential* or *primary* hypertension, or *hypertensive cardiovascular disease* (Janeway). The increased blood pressure is the essential or primary condition. Any changes which may be in the walls of the blood vessels, the heart, the kidneys or other organs are either a secondary result of the hypertension, or co-existent with it, and in the latter case may or may not be due to the same cause as is the hypertension.

Ætiology and Pathology.—The ætiology and pathology of hyperpiesia is obscure, and constitutes one of the most important and difficult questions in clinical medicine.

An inherited constitution is an important factor, as revealed by the high familial incidence in certain cases. The malady is more common in late middle life; in those who tend to worry, to be over-anxious, to take things too seriously, or are of an excitable disposition; in those whose manner of life involves continued mental or emotional stress or strain; and in the obese. It may be the result of poisons circulating in the blood, which act as pressor substances, such as occurs in endocrine disturbances, for example, at the female menopause, in tumours of the adrenal cortex or medulla, with Cushing's Basophilism Syndrome (pituitary basophilism), and in acromegaly; in focal sepsis; and in chronic alcoholic excess and excessive smoking. The general consensus of opinion is that a high protein diet intake in itself is not a cause, but in my view it is.

With regard to the pathogenesis of hyperpiesia, it is generally agreed that the immediate cause of the condition is an increased resistance to the passage of blood through the smaller arteries, especially the arterioles, at first due to hypertonus on their part. If the latter does not cease, either spontaneously or because of therapeutic measures, then, sooner or later, cardiac hypertrophy, especially of the left ventricle, and diffuse hyperplastic sclerosis supervene (see page 1035). The latter gives rise to actual narrowing of the lumen of the blood vessels, which may even be great, and a resultant further increase in the resistance to the passage of blood.

The cause of the initiation of the hypertonus of the arteries cannot yet be explained.

It is to be noted that some now consider that hyperpiesia is primarily of renal origin. Among the reasons adduced for this view are that some cases, in the course of time, develop into what is termed "malignant" hypertension. It may here be observed that this only occurs in a small proportion of cases. The matter will be dealt with further later on. Again, experimentally produced renal ischæmia in dogs, the result of the gradual narrowing of the renal arteries by means of clamps, will give a condition similar to hyperpiesia in man. With regard to this, it may be pointed out that pressor substances circulating in the blood from any source, including the kidneys, will have a like effect.

By far the general consensus of opinion—which I myself share—is that it is not possible to explain hyperpiesia as being due to structural changes in the kidneys, in which connection the following observations may be

made. (1) In hyperpiesia the blood pressure becomes normal under ether anæsthesia, and is diminished during sleep. (2) Hyperpiesia and diffuse hyperplastic sclerosis may occur independently of any renal lesion. (3) While in hyperpiesia and diffuse hyperplastic sclerosis the kidneys generally become involved secondarily, it may be in marked degree, with consequent increased obstruction to the circulation and an increase in the hypertension, in a large proportion of cases there is generally little or no impairment of renal function, which is one of the most characteristic features of hyperpiesia, and less than 10 per cent. die from renal failure. (4) There is frequently an absence of hypertension in polycystic and tuberculous disease of the kidney, occasionally in acute nephritis, and rarely in chronic nephritis. (5) In chronic nephritis changes may take place in the renal vessels of an almost exactly similar nature to those in diffuse hyperplastic sclerosis, leading to hypertension and similar cardiovascular accidents. But there the vascular changes are secondary to the nephritis.

Hypertension is not by any means only the result of kidney disease. There are many other causes. Indeed, it may even be asked whether in some cases of hypertension and diffuse hyperplastic sclerosis, and chronic nephritis, the former may have been the cause of the latter? Or, again, may both be the result of a common cause?

While the great majority of cases of hypertension are of the nature of hyperpiesia, the condition may also be due to diffuse hyperplastic sclerosis (see page 1035), chronic and acute nephritis, polycystic disease of the kidney, increased intracranial pressure, *e.g.* intracranial hæmorrhage, and polycythæmia vera. With regard to the first, however, the condition is rather the result than the cause.

Symptoms.—In hyperpiesia the patient is often well nourished and may be plethoric. There may be a complete absence of subjective symptoms for some years, and the condition may be discovered accidentally, *e.g.* during an examination for the purpose of life assurance.

Usually the onset of symptoms is insidious. The most common early symptoms are a feeling of fullness and it may be of throbbing in the head, transient giddiness, tinnitus aurium, flushing, insomnia, palpitation, languor and early fatigue, the latter especially on mental effort, headache, of a dull aching or it may be of a throbbing character, particularly in the occipital region and especially in the morning, impairment of memory, mental irritability and diminished emotional control. The blood pressure readings are above those mentioned in the first paragraph.

The condition may subside, either spontaneously or the result of therapeutic measures. If not, the blood pressure readings usually increase, and the systolic may reach 240 mm. or even more. Consciousness of the action of the heart may become more prominent. Sooner or later, there is evidence of hypertrophy of the heart, especially of the left ventricle, and of diffuse hyperplastic sclerosis (see page 994). The walls of the radial, the brachial and temporal arteries may be felt to be uniformly thickened—the so-called "whip-cord" artery. The degree of hardening of the arteries is found on palpation to vary at different times. The artery feels hardest when the vessel is most contracted and consequently smallest. The character of the pulse is that of high-tension. The retinal arteries are often thickened, and on ophthalmoscopic examination may show a glistening light along their

course—the so-called "silver wire" arteries, due to reflection of light from the thickened vessel. Even more important is a visible irregularity in calibre of the arteries best seen near the disc. Further, at the arterio-venous crossings there may be seen an obstruction to the flow of blood through it, leading to distension of the peripheral part of the vein and also to deviation of the vein where it crosses the artery.

The subsequent clinical picture and course exhibit considerable diversity.

The cardiac symptoms are by far the most common. The most frequent are shortness of breath, palpitation and precordial discomfort or pain, referred to exertion. Later, cardiac failure, usually left-sided but it may be involving both sides, may supervene (see page 857). Acute left-sided failure may occur (see page 857). Angina pectoris is not very infrequent. There is occasionally coronary occlusion. For further particulars, the reader is referred to page 857.

Various gastro-intestinal symptoms are often present. There may be hæmorrhages from the nose, the stomach, the intestines and other mucous membranes, the kidneys, the conjunctiva, and occasionally the retina, which are sometimes flame-shaped. There may be tingling, numbness and cramp of the limbs, and occasionally intermittent claudication. Hypertensive encephalopathy (see page 1607) may occur. Cerebral hæmorrhage may be a terminal event.

Not infrequently there is albuminuria, generally slight and not constant, and there may be polyuria and nocturnal micturition, and hyaline and granular casts. There is usually no or little impairment of renal function. Uræmia is rarely a terminal event.

There is a small group of cases of hypertension in which, instead of the symptoms being mild or moderate, the course slow, and little or no renal insufficiency, the symptoms are severe, the course is progressively rapid, and the patients die from renal failure. The former, which constitutes the great majority, is called benign and the latter "malignant" hypertension. There are also intermediate forms between the two groups. The renal changes in malignant hypertension are described as malignant nephrosclerosis, and those in benign hypertension may be termed benign nephrosclerosis. It may be remarked, however, that the term malignant is not altogether an appropriate one.

Malignant Hypertension.—There appear to be two forms of this, namely: (1) In a case of benign hypertension of a varying number of years' duration, the symptoms suddenly become severe and the malady pursues a rapid course. (2) In an individual who has not been aware that he had hypertension, from the outset there are severe symptoms in association with hypertension and the course is rapid. The second usually occurs at an earlier age than the first.

There are the same changes in the kidneys as in the benign form, and, in addition, those which are believed to be characteristic, *i.e.* acute necrosis of the walls of the arterioles and also often of the root of the glomeruli, and it may be resultant thrombosis of the glomeruli. While acute necrosis is most marked in the vessels of the kidneys it is also found in those of other organs. There has been much discussion among pathologists regarding the interpretation of the distinctive changes in the kidneys. In the opinion of some, they are an intensified result of the ætiological factor of the changes

in the walls of the arteries in the benign form; while others think they are due to a special toxin. Again, some are of opinion that malignant hypertension is merely a severe or extreme phase and a terminal result of the benign variety, whereas others think that it is a separate entity.

In malignant hypertension, the blood pressure, especially the diastolic, is usually materially higher than in the case of the benign form, being generally over 200–120, and may be very high and may become extreme. There is lassitude, anorexia, frequently loss of weight, severe headache and anæmia. Changes in the retina occur earlier and are more marked, hæmorrhages being more evident and retinopathy is frequent if not usual. There is polyuria and nocturnal micturition. The urine is of low specific gravity, and contains hyaline and granular casts, a variable amount of albumin and often red blood cells. As the disease progresses, there is evidence of renal impairment. Death occurs from uræmia, cardiac causes or cerebral hæmorrhage.

In hyperpiesia it is probable that more than half the patients die from cardiac causes—in the great majority from congestive failure, not infrequently from angina pectoris, and occasionally from coronary occlusion; in a fair proportion of cases, cerebral hæmorrhage is a terminal event; in less than 10 per cent. uræmia; while in the remainder the cause of death is some intercurrent disease.

Diagnosis.—Hypertension is recognised by persistent blood pressure readings above those mentioned in the first paragraph of this article.

The diagnosis between hyperpiesia and malignant hypertension may readily be made from a consideration of the respective clinical features described above. That between malignant hypertension and chronic glomerular nephritis may be difficult.

Prognosis.—Hyperpiesia usually pursues a slow course. It is probable that the duration of life after the beginning of symptoms is ten to fifteen years, or even more. The outlook is chiefly affected by the blood pressure readings, particularly the diastolic, the state of the heart and of the arteries, and the patient's manner of life. See also page 996. The duration of life in malignant hypertension is usually at the most two years.

Treatment.—As regards the treatment of hyperpiesia, the first indication is a thorough review of the ætiology. Then, the question as to whether a preliminary rest and, if so, how much is advisable should be considered (see page 862).

Hyperpiesia is an excellent example of the value of treating not only the disease but the patient. He should be reassured and encouraged. It is inadvisable to let him know the exact blood pressure readings at any time.

In no cardiovascular malady, excepting perhaps in angina pectoris, is the manner of life of so great consequence.

The cardinal indications are that, while the patient's activities should not be unnecessarily curtailed, they should come within the limits of his strength and even keep something in reserve; there should be a sufficiency of rest in his life; and all causes of mental and emotional stress should be carefully avoided. With this object in view, inquiry should be made regarding the patient's environment, the nature and hours of his work, his habits, the question of sleep and other relevent matters, while his temperament should be taken into consideration.

Each patient should be in bed for at least ten hours each night, rest physically and mentally for at least half an hour after the midday meal and have a quiet day each week. If the blood pressure is more pronounced, he should be in bed for at least twelve hours, rest for at least an hour after lunch, and stay in bed on one day a week with, it may be, a diet limited to vegetables, fruit and milk. In addition to an annual holiday of good length, several shorter ones during the year are advisable, in each case with a sufficient element of rest. As indicated, physical exertion and mental effort should be within the limits of the patient's strength (see page 863), with something in reserve. With this proviso, walking in the open air, riding a non-pulling horse, golf and mild bicycling are suitable forms of the former. The patient should be encouraged not to worry, or be over-anxious, or to take things too seriously; to avoid all excitement and other forms of emotional stress; and cultivate the art of "relaxing," physically and mentally.

If the patient tends to worry, or be over-anxious, or to take things too seriously, sedatives (see page 863) are often of special value. The matter of sleep is also of particular importance, and if there is insomnia, it should be treated on the lines laid down on page 863. Again, any obesity should, without fail, be corrected.

The amount of fluid with meals should be diminished, while an ample quantity should be taken between meals. Some prefer the mildly alkaline waters. The benefit of a regulated diet of moderate latitude may be considerable. Its amount should preferably be rather less than is needed. Those articles of food which especially stimulate the cardiovascular system should be reduced and proportionately to the degree of hypertension. The quantity of beef and mutton should be diminished, while twice-cooked meat, salted and preserved meat, liver, kidney, brains, sweetbreads, meat soup, and gravies, and meat extractives are better avoided altogether. Fish, poultry, game (not high), rabbit, vegetables, salads and fresh fruit are suitable. Ruthmol may be used as a substitute for table salt with meals. Moderation in the use of tobacco, tea and especially of coffee should be enjoined. Alcohol is better avoided altogether.

Strict attention to the condition of the bowels, preferably by a saline each morning, and a mercurial preparation at bedtime once or twice weekly are indicated.

Cold and hot baths are contra-indicated; but a warm bath, the temperature of which is gradually lowered, may be taken daily. A Turkish bath once or twice a week may be helpful. Patients often derive much benefit from a course of treatment at a Spa where different kinds of baths are used, on account of the rest, the change of air, the regular mode of life and exercise, the careful dieting and other factors, and in such cases periodic visits are to be recommended.

Iodine, in some form, in small doses appears to be occasionally of help. The same perhaps applies to the nitrites, such as a combination of sodium nitrite, erythrityl tetranitrate and mannityl hexanitrate, when symptoms are present. I have been disappointed with the results of the administration of mistletoe, liver extract, and potassium and sodium thiocyanate.

Diathermy, high frequency currents and other forms of physiotherapy are employed by some.

When the blood pressure is very much raised, particularly if there are

SECTION XIV

VASOMOTOR NEUROSES (ANGIO-NEUROSES)

INTRODUCTION

UNDER this heading are described several diseases in which vasomotor disturbance is the prominent symptom. Sensory, secretory and trophic disturbances may also be present. These diseases differ from each other both in regard to the nature and location of the vasomotor changes. Thus in Raynaud's disease there is a spasm of peripheral arteries. In erythromelalgia there is vaso-constrictor paralysis or excitation of the vaso-dilator nerves. In angio-neurotic œdema there is disturbance of capillary permeability, and perhaps of capillary tone. These diseases are described as vasomotor neuroses because a lesion of structure is not an essential part of their pathology, and because a considerable functional element is generally present. Thus they are common in persons who have an unstable nervous temperament, and emotional disturbance and fatigue play a not unimportant part in their ætiology. It has been thought in the past that these diseases were primarily due to disorder of the involuntary or vegetative nervous system. Lewis, however, has shown in the case of Raynaud's disease that a local fault of the vessels rather than a disordered vasomotor impulse determines the spasm of the digital vessels, and he finds the explanation of Raynaud's disease in terms of vasomotor dysfunction unconvincing. Too little is known of the ætiology of acroparæsthesia, erythromelalgia and Milroy's disease to throw light on this aspect but whatever the basic pathogeny of these conditions may be, vaso-dilatation is a prominent feature of erythromelalgia.

It is important that as far as possible a distinction should be drawn between these diseases occurring as neuroses and similar syndromes complicating recognised pathological states, such as lesions of the spinal cord or brain (tabes dorsalis or hemiplegia), lesions of peripheral nerves (peripheral neuritis), and lesions of vascular channels, or local pressure effects, such as may result from a cervical rib. But they are not separated by a rigid line from slighter manifestations of vasomotor instability, such as are frequent in women at the climacteric, and in clinical disorders resembling exophthalmic goitre. They are undoubtedly akin to such common symptoms as flushings, cerebral hyperæmia, facial congestion, angio-spasm in all its varieties, tachycardia (in some of its forms), anginal attacks, migraine, vertigo, tinnitus aurium, universal or circumscribed hyperidrosis, and gastric disorders of certain forms of functional gastric dyspepsia.

Lewis's studies on the local vascular reaction to irritation of the human skin have thrown much light on these diseases. He showed that there are three components in the reaction: (1) a primary dilatation of capillaries—the *red line*; (2) an increased permeability of these capillaries, producing the *wheal*,

which is independent of the nerve supply; and (3) the *flare*, which depends on the integrity of the sensory nerve fibres in the neighbourhood. All these phenomena can be produced by an intradermal injection of histamine, and he attributed them to the liberation of this or some similar chemical substance to which he gave the name of "H-substance." It has been suggested that local liberation of histamine may play a part in producing the vesicles in herpes and the rash in erythema nodosum. It is of special interest that these reactions are partially dependent upon and partially independent of the nervous system. Some of the angio-neuroses are therefore so closely related to allergy that a general description of that condition is called for here.

ALLERGY

Idiosyncrasy has been defined as an unusual physiological personal equation, and allergy is a chemical idiosyncrasy, which expresses itself as an urgent attempt on the part of the cell to conserve its chemical identity. The tendency to allergy is inborn, whereas anaphylaxis is an acquired sensitivity. All the phenomena of allergy can be reproduced by histamine. The question is, how does this substance, which is toxic to everyone, become liberated in the tissues of certain people in answer to stimuli which are quite harmless to everyone else? Normally there are two antagonists to histamine, adrenalin and the special ferment histaminase. It has therefore been suggested that the chemical basis of allergy is a congenital lack of histaminase, aggravated by an intermittent deficiency in adrenalin. The reaction is usually excited by foreign proteins, but a similar idiosyncrasy may be shown to various drugs.

The manifestations of allergy express themselves chiefly (*a*) in *the respiratory system*, by asthma, hay fever, paroxysmal rhinorrhœa, recurrent catarrhs; (*b*) in *the skin*, as urticaria, purpura and eczema, particularly of the infantile type; (*c*) in *the alimentary canal*, by diarrhœa and vomiting, or spastic colon; and (*d*) by *effusion into joints*. There are many other conditions which with more or less show of reason might be added to this list. Certainly some cases of migraine seem to be of this order. It will be noted that several of these manifestations could be interpreted as a violent attempt to expel the invader, at any rate from the vital organs.

Most allergic manifestations are worse at night, because of the prominence of vagus control then, so that there is a relative insufficiency of the sympathetic nervous system, and therefore in the supply of adrenalin. The principal conditions produced by allergy are described under their appropriate headings.

ANGIO-NEUROTIC ŒDEMA

Synonym.—Quincke's Disease.

Definition.—A paroxysmal affection, characterised by the appearance of circumscribed œdematous swellings of the skin and subcutaneous tissues of transient duration. The mucous membranes are often affected.

Ætiology.—Heredity is an important factor. Osler reported the case of a family in which five generations had been affected, involving 22

members. The condition is more common in men than in women, and generally affects the young. Those attacked are usually of a nervous disposition. Garrod reported a case in which each recurrence of periodic hydrarthrosis was attended by circumscribed œdema, either of the lips or eyelids. The attacks may coincide with menstruation. The exciting cause is generally difficult to determine. It may be emotional strain, exposure to cold, or trauma. Local trauma sometimes determines not only the onset but the site of an attack, as in a case recently reported in which riding provoked an attack on the inner aspect of the thighs and knees.

Pathology.—In the absence of a known pathology various theories have been advanced to explain the condition. Local venous spasm, a direct nervous influence on capillary walls, as a result of which the permeability of the vessels is increased, and, more recently, the local action of a circulating toxin on the capillary walls, are theories which have obtained support. With regard to the last named, Garrod drew attention to the joint swellings that frequently accompany erythematous and urticarial rashes resulting from known toxic causes. Such conditions form a part of the clinical picture of serum sickness, or may occur after taking certain articles of diet, or as the result of stings of insects or nettles. Lewis has shown that a modification of the same toxin may produce a dermolysin or a hæmolysin. In the former instance œdema; in the latter purpura results. Thus, *B. welchii* may produce either condition, depending on the intensity of the infection. This thesis illustrates the present view of angio-neurotic œdema as being a local expression of the presence of a circulating toxin, prone to occur in persons of nervous temperament, rather than a disease *sui generis*. The patients often show other signs of allergy, especially in their sensitiveness to foreign proteins.

Symptoms.—The complaint takes the form of acute circumscribed swellings of the skin and subcutaneous tissues, 1 to 4 inches in diameter. The swellings are rounded, painless, rarely itch, and are generally pale or sometimes redder than the surrounding skin, from which they stand out prominently. They may develop simultaneously in different parts of the body, and disappear in a short time. They may recur repeatedly, or only after a period of years; the recurrence is occasionally periodic. They occur most commonly in the eyelids, lips, cheeks and backs of the hands, and are asymmetrical. The whole side of the face, one side of the scrotum, the penis, a whole limb, or in fact any part of the skin, may be involved. The pharynx, tongue and conjunctivæ may be implicated. Œdema of the glottis is rare, and has proved fatal. Swelling of mucous membranes may lead to symptoms of gastro-intestinal disturbance, such as nausea, vomiting and colic. Cases in which hæmorrhage from mucous membranes, stomach, bronchi, bladder, etc., occurred have been reported. Hæmoglobinuria has been observed; in such a case a Wassermann test is indicated. The attacks are generally afebrile, and there is no constitutional disturbance, unless the stomach or intestine is involved.

Course.—This is variable. Recurrence is frequent, often at intervals of 3 to 4 weeks, but sometimes after long intervals. It is rarely periodic.

Diagnosis.—The complaint is so characteristic, in the sudden onset and rapid subsidence of asymmetrical rounded swellings, that it is hardly likely to be confused with other affections. The condition is nearly allied to

urticaria, from which it is distinguished by the circumscribed and deep-seated nature of the swellings and the absence of itching. No distinction is made between angio-neurotic œdema and giant urticaria.

Treatment. — The general health must receive first attention, and a saline purge is indicated. Both arsenic and quinine have been advocated. It is advisable to avoid any particular protein in the food which is found to excite attacks. When the attacks occur after a particular meal of the day, a capsule containing 1 to 2 grains of peptone half an hour before that meal appears to have an effect in temporarily desensitising the body against foreign protein. This, combined with 5 to 7½ minims of tincture of belladonna and 10 to 15 grains of calcium lactate after meals, has prevented recurrences in several cases. The former drug diminishes the vagal hypersensitiveness, and the latter increases the viscosity of the blood. One of the most useful forms of treatment for the relief of the paroxysm is a subcutaneous injection of 3 to 7 minims of liquor adrenalinæ hydrochloridi. This excites the antagonistic action of the sympathetic. For the same reason half a grain of ephedrine orally administered may be tried. When the tongue is involved the patient should be given one or two of Armour's suprarenal tablets to suck. Pituitary (posterior lobe) extract injections have also been recommended. Bromide is often helpful as an additional measure when the symptoms are marked. In severe cases the intravenous injection of small doses of peptone might be considered. Autohæmotherapy has proved decidedly useful in some cases. Vitamin K is also worthy of a trial.

Intermittent Hydrarthrosis, which is described under "Diseases of the Joints" (p. 1367), presents some interesting affinities with the vasomotor neuroses, particularly in its association with angio-neurotic œdema.

RAYNAUD'S DISEASE

Definition.—"Intermittent pallor or cyanosis of the extremities brought on by cold, with the skin a normal colour between attacks" constitutes Raynaud's phenomenon, which may occur however in conditions other than Raynaud's disease.

Ætiology.—The cause of this malady is unknown; it almost exclusively affects young women, and symptoms may begin any time between adolescence and middle age. The diagnosis of Raynaud's disease in a man is nearly always wrong. Jonathan Hutchinson preferred to speak of Raynaud's phenomenon, regarding it not as an entity but as a syndrome occurring in many different conditions. As he first suggested, a few cases are due to syphilis, congenital or acquired. It has occasionally been observed after acute infections.

Pathology.—Lewis has shown that there is an abnormality of the digital arteries, which expresses itself in a hypersensitiveness of these vessels to relatively low temperatures. It seems therefore that the fault lies primarily in the vessel wall rather than in the nerve supply to the muscle fibres. In advanced cases there is endarteritis, with partial occlusion of the lumen of the artery.

Symptoms.—The patients complain of attacks of pallor, blueness or numbness of the fingers, brought on by contact of the hands with anything

cold. Keeping the palms of the hands in cold water (15° C.) for 15 minutes in a cool room (18° C.) is usually sufficient to induce an attack. The body temperature is just as important, if not more so, than that of the hands in determining the onset of cyanosis. When such patients feel chilly in themselves their hands go blue on the slightest provocation, *e.g.* when sitting in a draught; when walking, cycling or driving a car in cold weather; or when swimming. When the body is really warm it is impossible to induce an attack no matter how cold the hands are. Emotion also may bring on an attack. In this connection it is interesting that an injection of adrenaline may have a similar effect. The attacks vary from slight pallor of one finger-tip to cyanosis and numbness of all the fingers of both hands. The cyanosis begins as a light-bluish tint, and later becomes a deeper blue. It always starts at the finger-tips, and spreads proximally to the base of the fingers and perhaps to the palm; rarely, if ever, does it reach above the wrist. If the attack persists for long, a secondary waxy pallor replaces the cyanosis. The hands remain blue or pale until they are warmed. They feel cold to the observer's touch. When the hands are warmed (40° C. for 3 minutes), or when the body temperature rises, the blueness begins to pass off, and irregular red blotches appear in its midst "like the spots on a plaice." Some of these appear and fade away, but in the end they coalesce until the dorsum of the hand and the palm are fiery-red or scarlet. Gradually this redness spreads up each finger from base to tip.

Throughout the period of cyanosis the patients complain of a "tingling" or of a "feeling of numbness" in the fingers; some of an "uncomfortable sensation"; some of a "slight pain"; severe pain is unusual. When warmth is applied in any form—hot air in front of a fire, or by friction—the fingers quickly recover their normal colour. During this stage there are paræsthesiæ, "pins and needles," etc. In only a few patients is sweating of the hands a marked feature during attacks. Swelling of the fingers is rare. In a severe attack local pressure on a finger leaves an indentation which takes longer to disappear than when the circulation is normal. While the hands remain cold the radial pulses are of smaller volume and the veins less prominent than when warm. If a finger is accidentally cut when cold it does not bleed; "only a little dark blood oozes out." If symptoms occur in the feet they are usually less severe than in the hands. Nutritional changes at the extremities are rare in true Raynaud's disease. But in the later stages, when secondary arterial changes in the arterial walls have occurred, small areas of superficial necrosis at the finger-tips may be found, which leave small depressed tender scars.

Diagnosis.—This has been considerably clarified by John Hunt. The first question to be answered is: Is the complaint "Raynaud's phenomenon"? *i.e.* Is there *intermittent* cyanosis of the extremities, brought on by cold, with the skin a normal colour between attacks? The following conditions with their vascular phenomena are eliminated by this simple definition, many of them because their symptoms are continuous and not intermittent: chilblains; frost-bite; acrocyanosis; erythrocyanosis; clubbed fingers and cyanosis of the fingers and toes due to lesions of the heart and lungs; enterogenous cyanosis; incipient gangrene from arterial thrombosis (in advanced arteriosclerosis, thrombo-angiitis obliterans, or ergotism); arterial embolism; diseases of the nervous system

(neuritis, poliomyelitis, syringomyelia, pyramidal lesions, and hysterical paralysis), cervical rib. If true Raynaud's phenomenon is present then the other conditions in which this phenomenon occurs must be considered:

(1) *Hereditary cold fingers.*—Many healthy young people find that their fingers go white and numb on exposure to cold. This is the commonest cause of Raynaud's phenomenon, and is local syncope in its simplest form. The onset is usually during childhood up to about the eighth year. Both sexes are affected, as are often members of the same family. These three points clearly differentiate the condition from Raynaud's disease.

(2) *After local injury or infection of the hands or feet, and in workmen using vibrating instruments*—pneumatic chisels, hammers, riveters, road drills, etc.

(3) *Scleroderma.*—This is diagnosed from Raynaud's disease by the following points: The fingers soon become stiff, and the stretched shiny skin cannot be picked up from the underlying tissues. Nutritional changes in the finger-tips are frequent. It is not confined to the extremities, and is much more rapidly progressive, painful and depressing than Raynaud's disease.

(4) *Syphilitic Arteritis.*—This may be diagnosed when Raynaud's phenomenon is associated with severe necrosis of the nose and ears, and when hæmoglobinuria is present. A blood Wassermann may be positive.

(5) *Other rare causes of Raynaud's phenomenon.*—Erythræmia is one.

Treatment.—Cold in any form should be avoided. The temperature of the body as a whole is almost more important than that of the hands and feet, and warm clothing is essential. The temperature of a living-room should be about 20° C. (68° F.). Cold water should be banned, and gardening in cold weather left to others. Gloves should be loose and long, overlapping the coat-sleeves. For people who work with their fingers, mittens are invaluable. A muff, a small hot-water bottle, or an electric heater in a handbag or pocket may be recommended. Cracks at the ends of the fingers may be covered with a collodion preparation, or with narrow strips of elastic adhesive plaster. The skin of the fingers may be kept soft by applying liquid paraffin. Care should be taken to avoid minor injuries to the fingers, and when these occur they should be treated at once. Boots or shoes should be of stout construction, allowing plenty of room for the toes, and stockings or socks should be thick and soft; two thin socks often keep a foot warmer than one thick one. Tight suspenders should be avoided. Bedsocks and hot-water bottles are helpful at night.

The number of drugs that have been recommended to relieve symptoms indicates how few are really valuable. Thyroid, calcium lactate or gluconate, potassium iodide, and belladonna are perhaps the favourites. In some patients physical therapy is needed to give relief: postural exercises; radiant heat, taking special care to avoid burns; contrast baths; intermittent venous occlusion by alternating positive and negative pressures; and galvanic baths. Sympathectomy is indicated when the attacks of cyanosis are causing definite distress or recur so frequently as to interfere with work, and when temperature tests suggest that there is a considerable degree of vasomotor tone. The immediate results of the operation are excellent; but after some months, perhaps two years or more, slight symptoms may return. In spite of this disappointment the great majority

of patients insist, even several years after the operation, that their hands are better than they were before it. The relief of major symptoms is due to removing from the vessels the burden of their normal vasomotor tone. The local fault in the vessels remains untouched, for on this the operation has no effect.

ACROPARÆSTHESIA

Definition.—A vasomotor neurosis, characterised by paræsthesiæ of the hands, especially affecting the finger-tips.

Ætiology.—The condition is usually observed in women, especially at the climacteric. It rarely occurs before the age of 30. It is frequently associated with a neuropathic diathesis and a lowered vitality due to any cause. General causes include inanition, anæmia and pregnancy. Local causes are exposure to cold, particularly cold water, or to alternate hot and cold water as experienced by washerwomen.

Symptoms.—The onset is insidious and the symptoms are almost entirely subjective. The affection is often limited to one hand or certain fingers, the toes rarely being affected. The patient complains of numbness, tingling, formication of the fingers or tenderness of the finger-tips. There may be slight loss of sensibility in the finger-tips and occasionally evident pallor.

Diagnosis.—The condition is readily distinguished from Raynaud's disease by the absence of local asphyxia. It is important to exclude any affections of the spinal cord, such as tabes dorsalis.

Prognosis.—The complaint tends to be continuous and persistent. The outlook regarding recovery is not good, unless the condition is due to a recognisable and removable cause. There are, however, no complications.

Treatment.—This is directed to the removal of the cause, and improvement of the general health and of the local circulation. Sodium salicylate and bromides are often helpful, and radiant heat and massage are of value.

ERYTHROMELALGIA

Definition.—A rare condition characterised by pain, redness and swelling of the toes and feet, and less often of the hands.

Ætiology.—Little is known of the ætiology of the disease. Men are more often affected than women. The condition may occur in the course of a disease of the central nervous system, such as hemiplegia, disease of the cauda equina, and disseminate sclerosis. The swelling and pain are aggravated by standing and by warmth.

Pathology.—Disease of the peripheral arteries—a chronic endarteritis—has been described in three cases by Batty Shaw. Changes in the peripheral nerves have been held responsible, and Weir Mitchell found marked degeneration of the fine nerve branches in one case. Others regard the malady as an angio-neurosis, allied to acroparæsthesia and Raynaud's disease. Lewis prefers to regard erythromelalgia as a special instance of a condition he designates as *erythralgia*, which he maintains has nothing to do with abnormality of the vasomotor system, but always results from a local process.

There is a release into the skin of an unknown substance not histamine, which lowers the threshold of the pain nerve endings.

Symptoms.—The first case was described by Weir Mitchell, and was that of a sailor, aged 40, whose first complaint, following an African fever, was of "dull, heavy pains at first in the left, and soon after in the right foot. There was no swelling at first. When at rest he was comfortable, and the feet were not painful; after walking the feet were swollen. They scarcely pitted on pressure, but were purple with congestion; the veins were everywhere singularly enlarged, and the arteries were throbbing visibly. The whole foot was said to be aching and burning, but above the ankle there was neither swelling, pain . . . nor flushing."

Pain is generally the first symptom, soon followed by redness and swelling, most marked in the terminal phalanges of the toes or fingers. The pain is generally severe; at first it occurs only in the evening, but later it becomes chronic or remittent and may be agonising. The redness may increase to cyanosis. The swelling is more marked in the latter part of the day, and is aggravated by standing, walking, dependence of the limb and by heat. These symptoms are relieved by cold and recumbency. Hyperidrosis of the affected part is not uncommon. The condition may be complicated by general weakness, vertigo, headache, palpitations and tachycardia. Its complication with erythræmia has been described. Pellagra has been mistaken for erythromelalgia.

Prognosis.—The complaint is intractable, and tends to persist, with exacerbations and remissions, for many years.

Treatment.—The affected part should be elevated and immobilised. Faradism and cold have been recommended. Analgesics are required for the relief of pain, which may even necessitate amputation (Shaw). Sympathectomy is contra-indicated and should never be performed for this condition.

ERYTHROCYANOSIS

This condition occurs, as its full name, Erythrocyanosis Crurum Puellarum Frigida, implies, chiefly in the legs of young women. The feet and legs are cold, and the back of the leg and ankle is swollen and blue, especially at the insertion of the tendo Achillis. Chilblains are often present, and ulceration may occur where the swelling is most severe. The condition is due to vascular spasm, in which the modern fashion of inadequately protected extremities is presumably a factor. Treatment includes warmer stockings, with silk ones outside to gratify the usual desire for appearance, and the loosening of all tight bands above and below the knee. Exercises, such as walking and skipping, with local massage should be ordered, and elevation of the heel may give some relief. Calcium gluconate, vitamin D and small doses of thyroid have been advocated, and daily subcutaneous injections of acetyl choline bromide, beginning with $\frac{1}{4}$ c.c. and gradually increased to 1 c.c., have given good results. After a fortnight the injections may be administered less frequently, and at the end of six weeks discontinued. Bilateral lumbar ganglionectomy has been recommended, but should not be considered unless thorough medical treatment fails. It may improve the colour of the skin and promote healing of any ulcers, but it does not diminish the swelling.

CAUSALGIA

This is a form of neuralgia usually following injuries in the neighbourhood of certain nerves, particularly the median and sciatic. It is probably due to irritation of the peri-arterial sympathetic fibres. On account of the burning character of the pain, Stopford has suggested the name *thermalgia*. The malady is fully described under lesions of the median nerve.

MILROY'S DISEASE

Synonym.—Hereditary Œdema.

Definition.—In 1892, Milroy described a persistent œdema of the legs, occurring in the absence of any of the known causes of œdema, affecting members of the same family in successive generations.

Ætiology.—The disease has occurred in six generations of the same family, but the percentage of incidence in the families has varied greatly. It is apt to appear in neurotic families. Both sexes are affected about equally, and the œdema may either appear soon after birth, or its onset may be delayed till puberty or even till adult life. Thirty-five years after his original description, Milroy found that the disease was tending to die out in the family in which he first observed it.

Pathology.—Nothing is known of the pathology of the condition. There is no evidence of venous or lymphatic obstruction.

Symptoms.—Only the legs are affected, and these to a variable extent. Thus the swelling may be limited to the ankles; it usually does not extend beyond the knees, but may reach the thighs in long-standing cases. It never extends above Poupart's ligament. Gradually the affected part becomes hard and brawny. The swelling increases in the standing posture, and, once established, it is permanent. There is no pain or redness, the veins are not enlarged, and the general health is not affected.

In some cases there are acute attacks accompanied by fever and pain. During this phase the condition resembles erythromelalgia.

Diagnosis.—This is made on the familial incidence, and the absence of all other recognised causes of œdema. A group of cases in which there is swelling of the feet, ankles and legs without albuminuria or discoverable organic disease to account for the swelling, has recently been recognised by Osman. The patients the writers have seen have been women in the third decade. The swelling is pale, brawny, and does not pit on pressure. This type may respond to rest in bed and intensive alkali therapy.

Prognosis.—The affection does not tend to shorten life.

Treatment.—The affected parts should always be kept bandaged with crepe, as by this means the swelling can be kept under control, and the patient remains able to lead an active life; but if such measures be not employed the œdema gradually extends. Acute attacks may require opium internally, and evaporating lotions locally.

W. Langdon-Brown.
Geoffrey Evans.

SECTION XV

DISEASES OF THE RESPIRATORY SYSTEM

THE PHYSICAL SIGNS IN THE CHEST IN HEALTH AND DISEASE

ACCURATE diagnosis in diseases of the air-passages and lungs depends largely upon careful observation and record of physical signs, especially in their relation to subjective symptoms. Unfortunately, there is no strict uniformity in regard to the nomenclature of physical signs. It is, therefore, desirable to define explicitly the sense in which the various technical terms used in this section are employed. At the outset, it is well to emphasise the importance of a careful and methodical examination in every case. The magistral sequence of inspection, palpation, percussion, auscultation and mensuration has more than the sanction of tradition to commend it. Unless confined to bed, the patient should be examined both in the erect and recumbent positions in all cases of difficulty.

INSPECTION.—The patient being placed in a good light, the configuration of the chest, the range and character of the respiratory movements and the position of the cardiac pulsations should be carefully noted. Most of the terms used in this connection, such as flattening, retraction, recession of intercostal spaces and diminished movement are self-explanatory.

The respiration may be unduly slow (bradypnœa), rapid (tachypnœa) or distressed (dyspnœa). Dyspnœa may be inspiratory, expiratory or spasmodic. A peculiar periodic disturbance of the respiratory rhythm is that referred to as Cheyne-Stokes breathing. In this condition, the respiratory movements wax and wane in short periods of dyspnœa, each followed by an interval of apnœa or cessation of respiration lasting up to 30 or 40 seconds. It is due to deficient aeration of the blood and is met with in respiratory, cardiac and renal disease, and also in cerebral lesions and after some poisons.

A variety of grouped breathing is Biot's breathing, sometimes seen in tuberculous meningitis. The hyperpnœic period consists of a few breaths, deep or of increasing depth, followed by apnœa without the waning.

Certain abnormal forms of chest configuration are described: The *alar*, phthinoid or pterygoid type of chest is long, narrow and flat, with winging of the scapulæ; the subcostal angle is narrow and the upper interspaces are wide. The *emphysematous* or barrel-shaped chest is broad and rounded, the angle of Louis is prominent, the subcostal angle is wide, and the movements are restricted. The *pigeon breast* is characterised by prominence of the sternum, with sloping anterior thoracic walls. The *funnel breast* is

the converse of this, with depression of the lower end of the sternum and of the cartilages attached to it.

PALPATION.—Vocal fremitus or tactile fremitus is the vibration felt over the lung when the hand is placed flat upon the chest-wall without pressure and the patient says "ninety-nine" or some other resonant syllables. Vocal fremitus may be increased, decreased or absent in disease.

Tussive fremitus.—The similar vibration felt during cough.

Rhonchal fremitus.—The vibrations communicated to the chest-wall by sonorous rhonchi in bronchitis, and felt by the hand.

Friction fremitus or pleural fremitus.—A rubbing sensation communicated to the palpating hand in certain cases of dry pleurisy. A similar fremitus is occasionally felt in pericarditis.

PERCUSSION.—This consists in tapping the chest-wall over the lung and observing the note produced and the sense of resistance felt. Percussion may be *direct* on to the chest-wall or *mediate*, when the tap is made on to a finger or an instrument placed on the chest. The applied finger or instrument is called the pleximeter, the tapping finger or instrument, the plessor. Percussion should always be light, except over very muscular parts of the chest.

Normal resonance is the note obtained over healthy lung tissue.

Hyper-resonance is an increased resonance, with diminished sense of resistance obtained over emphysematous lung tissue.

Dullness is diminution or loss of resonance, with increase in the sense of resistance. Various degrees of dullness are described, such as impaired percussion, slight dullness, flat, wooden or stony note.

Tympanitic resonance—a hollow drum-like note.

Skodaic resonance—a clear, high-pitched note intermediate in character between the hyper-resonant and tympanitic notes.

Cracked-pot sound—or *bruit de pot fêlé*—a hollow note with a slight jingle added to it, obtained by smart percussion over a fair-sized cavity. It is also heard on percussion of a crying baby.

AUSCULTATION.—The breath sounds should be listened to first, then the adventitious or added sounds, and lastly the vocal resonance.

(*a*) BREATH SOUNDS.—The following varieties of breath sounds may be differentiated:

Vesicular breathing.—The normal respiratory murmur or faint rustling sound audible during inspiration and expiration, the former phase being two or three times as long as the latter. The pause between inspiration and expiration is short.

Cog-wheel, jerky or interrupted breathing is a form of vesicular breathing in which inspiration waxes and wanes, or is divided into two or more parts.

Harsh, exaggerated or puerile breathing.—An intense form of vesicular breathing heard in children and in some forms of emphysema.

Vesicular breathing with prolonged expiration.—There is no alteration in the intensity or pitch of inspiration, but expiration is more prolonged and often harsher.

Absent, diminished, weak and suppressed breathing are self-explanatory.

Bronchial breathing.—The pitch of both inspiration and expiration is raised. Expiration is as long as inspiration and is separated from it by a distinct pause.

Broncho-vesicular and vesiculo-bronchial breathing are incomplete forms of bronchial breathing in which inspiration or expiration respectively assume the bronchial type.

Tubular breathing is a peculiar form of high-pitched bronchial breathing of whiffing character, sounding as if produced close under the stethoscope. This term is often used as if synonymous with bronchial breathing, but should be restricted to breathing of the type just described, which is only heard in consolidation from lobar pneumonia and broncho-pneumonia and in collapse of the lung.

Cavernous breathing is bronchial in type, but both inspiration and expiration have a peculiar hollow character. Expiration is more hollow and more prolonged than inspiration.

Broncho-cavernous breathing is incomplete cavernous breathing, inspiration being bronchial, while expiration is cavernous.

Amphoric breathing.—An intense form of cavernous breathing, often having a very hollow metallic sound.

(*b*) ADVENTITIOUS SOUNDS.—These were formerly divided into dry and moist. The former are now called rhonchi, the latter râles.

Rhonchi are musical sounds produced by the passage of air over mucus or muco-pus in the bronchi. Those arising in the larger tubes are called sonorous rhonchi, those in the smaller tubes sibilant or whistling rhonchi.

Râles are bubbling or crackling sounds produced in the bronchi or alveoli by the passage of air through fluid exudate or secretion. They are usually divided into bubbling and crackling râles. Bubbling râles are heard when the lung tissue is still spongy. Crackling or crepitant râles are produced in consolidated or softening areas of lung. Both varieties are arbitrarily subdivided into fine, medium and coarse râles. Crepitant râles are sometimes referred to as "creps"; this practice may lead to confusion with crepitation and is better avoided. Crepitant râles were formerly called consonating, bubbling râles non-consonating. Gurgling râles are coarse, low-pitched râles, usually heard over a cavity, especially after a cough.

Crepitations are fine "hair-like" crackling sounds. They may be produced either in the pleura or in the lung. In the latter they occur only in pneumonia, broncho-pneumonia, collapse and œdema. They are heard chiefly with inspiration and may be increased in number and intensity by coughing. A coarse variety heard in resolving pneumonic lung is called redux crepitation.

Pleural crepitations are fine sounds of similar character occurring in the early or dry stage of pleurisy. They are heard rather towards the end of inspiration and are usually unaffected by cough.

Friction is a coarse rubbing, creaking or grating sound heard in pleurisy when there is rough exudate on the pleural surfaces. It may occur with either inspiration or expiration or with both.

Stridor is a loud, coarse sound, heard chiefly during inspiration in cases of obstruction of the larynx, trachea or main bronchi. It is louder and lower pitched than a rhonchus.

Post-tussive suction is a hissing sound, audible directly after cough. It is heard only over a cavity, and is caused by the influx of air to replace that expelled by cough.

Veiled puff of Skoda is a puffing sound heard towards the end of inspiration. It is said to indicate small and sacculated bronchiectatic dilatations.

Metallic tinkling and amphoric echo are terms used to describe the quality of certain sounds produced near a very large cavity or a pneumothorax, in breathing or coughing, or by the heart's action.

Succussion splash is a splashing sound produced in a hydro- or pyopneumothorax by shaking the patient, or getting him to shake his thorax. If a gastric splash can be excluded, it is pathognomonic of a pleural or subphrenic hydro- or pyopneumo-thorax.

Bell sound or *bruit d'airain.*—A ringing sound heard on auscultation over a pneumothorax or any large cavity when a coin placed flat on the chest-wall over the air-containing space is tapped by a second coin. A similar sound is often audible on flicking with the finger and thumb over the chest-wall under similar conditions.

Voice Sounds or Voice Conduction.

Vocal resonance is the muffled sound on listening over normal lung when the patient articulates " ninety-nine " or some other resonant syllables.

Bronchophony is an increase in the intensity of the normal vocal resonance.

Pectoriloquy is conduction of the articulate voice sounds which are clearly heard as if spoken into the stethoscope. It is best appreciated by auscultating the whispered voice, and is then called whispering pectoriloquy.

Ægophony denotes a peculiar bleating or nasal modification of the voice sounds, sometimes heard on listening to them through fluid in the pleural cavity.

Physical examination of the chest includes mensuration, estimation of vital capacity and examination by the X-Rays when these are necessary.

Vital capacity is determined by a spirometer, which measures the amount of air which can be expired by a full expiration after the deepest possible inspiration. The average for an adult man is about 3600 c.c. The vital capacity is diminished in many diseases of the respiratory system, notably in acute pneumonia, pulmonary tuberculosis and in attacks of asthma.

R. A. Young.
G. E. Beaumont.

DISEASES OF THE NOSE

ACUTE CATARRHAL RHINITIS

See The Common Cold, p. 133

CHRONIC CATARRHAL RHINITIS

Ætiology.—Simple chronic rhinitis appears to result from frequently occurring attacks of coryza, or even from the persistence of a single acute attack. Predisposing causes of this persistence are deficient resistance, local irritation, auto-intoxication from the gastro-intestinal tract, and reflex vasomotor disturbance. Thus we find chronic catarrh associated with

anæmia, stuffy and over-heated rooms, occupations involving inhalation of irritating dust or vapour, excessive smoking, snuff-taking (a commoner habit than is generally realised among shop-assistants and clerks who are prevented from smoking during working hours), dyspepsia and constipation, alcoholism, sexual excess and masturbation. Nasal obstruction is an important factor in keeping up chronic catarrh by preventing ventilation of the passages, allowing mucus to collect and encouraging the growth of micro-organisms. In children the presence of adenoids is the commonest cause of catarrh.

Symptoms.—The symptoms are nasal obstruction and excessive secretion, which may be watery or muco-purulent, and may come forwards to the nostrils or pass backwards into the throat ("post-nasal catarrh"). Secondary results, from the extension of the inflammation, include catarrhal and suppurative otitis media, pharyngitis, laryngitis and bronchitis.

The nasal mucosa may be reddened, but often has a pale, sodden appearance. The turbinals are swollen and are at first quite soft, but later, when definite thickening has occurred, they feel firmer, and no longer shrink after the application of cocaine or adrenaline. At this stage the condition may be called "hypertrophic rhinitis," and the mucosal thickening, most marked over the two ends of the inferior turbinals and over the lower margin of the middle turbinal, may form large lobulated masses.

Diagnosis.—The diagnosis, in cases of hypersecretion, can only be made after excluding by rhinoscopic examination all other causes, such as a foreign body, mucous polypus, syphilitic, tuberculous and lupoid ulceration, and, more especially, suppuration in any of the accessory sinuses; in the latter, the discharge is not scattered over the nasal passages, but emerges in a localised stream from one or other of the ostia and reappears in the same situation after being removed. The discharge of chronic rhinitis is bilateral, and, though often muco-purulent, is never true pus. The diagnosis from vaso-motor rhinorrhœa is often difficult; the symptoms of the latter come and go with great suddenness, often as a result of definite causes such as going into a hot room, and there is complete absence of symptoms between the attacks. A bacteriological examination is often helpful.

Treatment.—General treatment, directed to the predisposing causes mentioned above, is necessary if a good result is to be obtained. Next, nasal obstruction must be removed, and operative treatment is called for if the cause be adenoids, deviation of the septum, or great hypertrophy of the extremities of the inferior turbinal bodies. For details, the reader is referred to surgical works; but it must be emphasised that the valuable secreting surface of the nasal mucosa must not be recklessly sacrificed, and that large portions of inferior turbinal must on no account be removed, nor should every slight deviation of the septum be submitted to operation, for it is rarely quite straight. When the turbinal enlargement is soft and shrinks after the applications of cocaine, the galvano-cautery should be used under local anæsthesia to draw one or two lines along the length of the inferior turbinal, the result of which is to produce a scar binding the mucosa to the bone. When the case has not gone on to definite hypertrophy, the most valuable form of local treatment is cleansing of the nasal passages. The lotion must be warm, about 90° F., and quite unirritating; for this reason it should have approximately the same specific gravity as serum, and

normal saline solution does very well. A mildly antiseptic and alkaline lotion is usually preferred, of which Dobell's solution is the type, such as sodium bicarbonate, grs. 3; sodium chloride, grs. 3; phenol, gr. 1; glycerin, min. 45; water, fl. oz. 1. A convenient instrument for the purpose is a small rubber ball of a capacity of 2 oz. with a blunt nozzle moulded in one piece, which is slowly emptied into the nostril, while the patient breathes deeply through the mouth and inclines the head forward over a basin; in this way the palate is raised and the lotion passes through the naso-pharynx and out by the other nostril. The nose must not be violently blown afterwards, nor must any force be used during syringing, or fluid may be injected into the Eustachian tubes. Occasionally syringing causes headache, in which case the lotion may be used in a coarse spray-producer. Chronic nasal catarrh is, however, in certain cases notoriously resistant to treatment, especially under the conditions of civilised town life; indeed, many sufferers found themselves better in the wet and exposed conditions of life in the trenches during the War of 1914–1918. Vaccine therapy is uncertain in its effect, but gives good results in a proportion of cases; an autogenous vaccine should be prepared from the patient's nasal secretion.

ATROPHIC RHINITIS

Synonym.—Ozœna.

Ætiology.—Cases usually first come under treatment between the ages of 15 and 18, but its insidious beginnings date from an earlier age, and a history of nasal discharge through childhood is often obtainable. It affects females at least three times as often as males. A peculiar physiognomy is to be noticed in nearly half the cases; the skull is brachycephalic, the nose wide and flat, and the nostrils broad and so directed forwards as to be more than usually conspicuous. The affection is sometimes unilateral, in which case the septum is deflected and the disease occurs on the wider side. Occasionally it is found among several members of a family, which might be the result of contagion, but it is also inherited in circumstances where contagion cannot apply, and this may be due to inheritance of the disease or merely of the predisposing physiognomy. It is more often seen in the poorer than in the more well-to-do classes and, in England, it has become much rarer during the last twenty or thirty years. Of the many bacteria found in association with the affection, the most important are the Klebs-Loeffler bacillus, the *Cocco-bacillus fœtidus* of Perez, and the *Cocco-bacillus mucosus* of Beeritz, but the consensus of opinion is that they are secondary, and, though helping to produce the fœtor, are not the primary cause of the disease. The condition occurs at too early an age to be the final stage of hypertrophic rhinitis, nor is it usually due to accessory-sinus disease, which can be excluded in the majority of cases. It is probably the sequel of prolonged purulent rhinitis in childhood, which results in the replacement of the ciliated by squamous epithelium, and thus destroys the principal agent for the removal of secretion; the undue width of the nasal passages promotes this retention by diminishing the force of the expulsive current of air, by drying the secretions and by unduly admitting dust and micro-organisms. In this way crusts of dried mucus are formed and decompose, and the resulting inflammation prevents the

development of the turbinals and thus further increases the width of the nasal fossæ.

Pathology.—There is a chronic inflammation resulting in sclerosis and atrophy of the mucosa; the ciliated epithelium is replaced by squamous, the mucous glands are degenerated and the venous sinuses have disappeared. These changes are most marked over the inferior turbinals; the middle turbinals are frequently large and œdematous. The discharge is not pus, but mucus precipitated by evaporation, mixed with shed epithelial cells and teeming with micro-organisms. This collects and dries into large greenish-black crusts which give rise to the peculiar sweetish and horribly offensive odour. There is never true ulceration nor necrosis of bone.

Symptoms.—The symptoms are chiefly those of the nasal discharge and the offensive stench; the latter is rarely perceptible to the patient, who usually, in established cases, has complete anosmia. There are also obstruction from the crusts, dryness of the throat and cough, and often some degree of ill-health from toxic absorption.

The inside of the nose is full of crusts; the inferior turbinals are reduced to mere ridges, the mucosa is pale and thin, and through the widened nasal passages the body of the sphenoid and the wall of the pharynx are plainly visible.

Complications.—Infection of an accessory sinus may result by extension from the septic nasal cavities, but is not very common; conversely suppuration of the sphenoidal or a posterior ethmoidal cell is a possible, and has been considered by some authorities as the usual, cause of the affection. The lymphoid tissue of the throat is conspicuously absent; there is often a dry pharyngitis and laryngitis, and sometimes the crusting extends to these parts, or even down the trachea. Catarrhal and suppurative otitis are common, and the disease is thought by many to predispose to pulmonary phthisis.

Prognosis.—As the ciliated epithelium can never be replaced, the affection is not truly curable, though regular treatment can keep it in an inoffensive condition, and it is common to see a suggestive degree of atrophy of the turbinals in young people with rhinitis completely disappear under treatment. Also, the crusting tends to become less troublesome as time goes on and ultimately to cease, a state of things which is difficult of explanation.

Treatment.—The nose must be kept clean by regular syringing with a mild alkaline antiseptic lotion, of which a large quantity should be used with a Higginson syringe provided with a fine nozzle which cannot block the nares. An oily, stimulating or emollient application, such as oleum eucalypti 15 minims to 1 ounce of paraffinum liquidum may be applied as a paint or spray, or a 25 per cent. solution of dextrose in glycerin as a paint. The crusting can be prevented by excluding the air and, when syringing is insufficient, this should be done by introducing a plug of gauze or cotton wool loosely into the anterior nares, which should be changed twice a day by the patient. After some weeks of treatment the packing may be omitted, but resumed in the event of a relapse. When the surgeon removes the plug the discharge is seen to be a clear mucus; if pus be found, it must be traced to its source in an accessory sinus. Paraffin wax may be injected under the mucosa, to narrow the nasal passages, but it is liable to slough out, and a piece of costal cartilage has been implanted with the same object. A plastic operation

has been devised to shift the antro-nasal wall inwards and has given encouraging results. The treatment of anæmia is important; good food and an open-air life, especially at the seaside, are beneficial.

EPISTAXIS

Ætiology.—The causes of epistaxis may be classified as follows:

Local causes.—Traumatism, including blows on the nose, fracture of the base of the skull, surgical operations and foreign bodies; the small septal erosion of rhinitis sicca, which is the commonest of all causes; malignant disease; angio-fibroma, or "bleeding polypus," of the septum; multiple telangiectasis, a curious hereditary affection characterised by numerous minute dilatations of the capillaries on the face and mucous membranes of the nose, mouth and throat; the general congestion caused by adenoids; and syphilis, lupus and the rarer granulomata, though in these the bleeding is usually an insignificant symptom.

General causes.—High blood pressure, as in arterial disease, chronic nephritis, cirrhosis of the liver, violent exertion, extremes of heat and cold, congestion at the menstrual period or "vicarious menstruation"; venous congestion, as in mitral stenosis, tumours in the thorax or root of the neck, emphysema, bronchitis and whooping-cough; toxic blood conditions, as pernicious anæmia, leukæmia, purpura, scurvy, and all the acute infectious fevers, especially in the prodromal stage. To these may be added rarefaction of the air, as in aeroplane ascents and mountaineering, and poisoning by some drugs, especially salicylates and quinine.

The *source of the bleeding* is, in the large majority of cases, in a region called Little's or Kiesselbach's area, situated on the front and lower part of the septum just beyond the vestibule.

Treatment.—Epistaxis, of sufficient severity to call for the attention of the doctor, should always be treated, though it is of comparatively little importance in healthy young people; in older patients with high blood pressure the loss of blood may be beneficial, but the occurrence is so distressing and alarming to the patient that other means to lower the pressure should be adopted.

The source of the bleeding is usually so far forward that a pledget of wool introduced for less than an inch into the naris, and held by compressing the nostril, will generally control it temporarily. To arrest it and prevent recurrence the bleeding spot must be found, started if necessary with a probe, controlled by application of cocaine and adrenaline on a plug of wool, and sealed by the galvano-cautery at dull-red heat. The use of an emollient ointment during the separation of the scab is advisable. In obstinate cases the bleeding may recur from another spot or from the opposite naris, when the treatment must be repeated. As in other forms of hæmorrhage, a rapid excited heart's action, associated with restlessness and fright, is often present, and an injection of morphine is of great value. Calcium lactate is often recommended and may be given in 20-grain doses three times a day for 2 or 3 days; or colloidal calcium may be injected subcutaneously. If the bleeding is from the usual situation, formal plugging of the nose is seldom called for; but sometimes the bleeding proceeds from farther back in the nose, or is so

profuse that its situation cannot at first be determined. In such cases the naris should be evenly packed with ribbon-gauze introduced on forceps under inspection. The older method of plugging the posterior nares is seldom required, and carries the risk of causing otitis media. Nasal plugs quickly become septic, and should ordinarily be removed in 24 hours; but they may be kept sweet for several days, should it be necessary to retain them, by moistening them frequently with peroxide of hydrogen.

MUCOUS POLYPUS

Ætiology and Pathology.—Nasal polypi are rare before puberty and are somewhat commoner in men than in women. They never grow from the septum, inferior meatus or inferior turbinal, but only from the ethmoidal region and interior of the accessory sinuses. They are not neoplasms, but are essentially due to a local œdema of the mucous membrane; the swelling thus produced is acted upon by the expulsive forces of the nose, and, being so pulled down and elongated, the return flow of its blood vessels and lymphatics is further impeded and a greater degree of œdema results. All stages of polypus formation may be found, ranging from an œdematous fringe along the border of the middle turbinal to enormous pedunculated masses which block the nose and expand its bony walls. In the majority of cases the œdema is due to inflammatory infiltration of the muco-periosteum of the ethmoidal labyrinth and is often associated with inflammation in the ethmoidal cells; sometimes, however, the cause is vasomotor disturbance, for polypi are found in cases of hay fever and paroxysmal rhinorrhœa in the absence of true inflammation. There is also another form, the so-called "choanal polypus," in which a large single polypus hangs into the naso-pharynx from a long pedicle attached within the antrum and passing through the ostium into the nose.

Symptoms.—The cardinal symptoms are nasal obstruction and discharge, which is profuse and watery. The symptoms are worse in damp weather. Cough, headache and asthma are not infrequent, and a loss of the power of mental concentration often occurs.

Polypi are smooth, shiny, white, translucent bodies, pedunculated and extremely soft and movable to the probe; their appearance is so characteristic that they cannot properly be mistaken for anything else. If they project into the nostril they become pinker and more opaque.

Treatment.—The best method of removal is in most cases with a wire snare, a process which can be rendered quite painless with skilful manipulation and the application of cocaine. Any polypoid mucosa in the neighbourhood should be removed with punch-forceps, but the application of caustics or the cautery only does harm. Recurrence is common, but becomes less rapid if the new polypi are removed at regular intervals before they have grown large. Inflammatory disease in the ethmoidal cells and other sinuses must, of course, receive treatment. In the worst cases, the polypi are so numerous and return so rapidly that the snare cannot deal with them adequately; in such they should be removed with a ring-knife or suitable forceps under general anæsthesia, together with the softened ethmoidal tissue, and any suppurating sinuses be opened at the same time.

PAROXYSMAL OR VASOMOTOR RHINORRHŒA

Synonym.—Allergic Rhinitis.

In this condition fits of sneezing are associated with a profuse watery nasal discharge, irritation of the nasal and conjunctival mucosa, nasal obstruction, and often marked depression and prostration. The discomfort is usually worse in the morning, in overheated rooms, or on going out into the cold. The rapidity with which the attacks come and go is sufficient to distinguish them from an ordinary coryza. The affection usually shows itself in early adolescence and tends to improve with advancing age; it is distinctly hereditary and is often associated, either in the patient or in his relations, with other symptoms of allergy, such as asthma, urticaria or chilblains. Males and females are equally affected, and it is most frequent among the cultivated classes; a mental shock is sometimes the starting-point of the attacks.

Of these cases, *hay fever* is the best known and most marked variety, and is due to specific susceptibility to a proteid substance contained in the pollen of certain grasses; in this country, attacks begin about the end of May and terminate in August. Hay-fever subjects are affected by very minute quantities of this toxin, whereas ordinary people are completely immune. Other individuals are susceptible to the pollen, seedlets or scent of other plants and flowers, and others again to the emanations from horses, cats, dogs and other animals; and researches show that asthma, urticaria, eczema or rhinorrhœa may be variously produced by many kinds of proteid substances, including common and uncommon articles of diet, such as eggs or lobsters, in certain people who are specifically susceptible to these substances.

Treatment.—The determining factors, which should receive attention, are heightened irritability of the nervous system, occasionally some intranasal abnormality which increases the sensitiveness, and the specific irritant. Nervine tonics, strychnine, arsenic and valerian, are indicated, and attention to the general health. Hay-fever patients are better in a locality as free as possible from pollen; some remain comparatively well at the seaside, others only on board ship, while some have to spend the best days of the year in a darkened room. Occasionally great benefit results from the removal of some nasal abnormality, a polypus or a sharp spur impinging on the turbinal, but the result of operative treatment is uncertain. In most cases the nares are normal, and in many of these a light cauterisation of the most sensitive areas is very helpful; the sites usually chosen are on the upper anterior part of the septum, and on the anterior part of the inferior turbinal. Ionisation of the nasal mucosa with sulphate of zinc is also employed. True hay-fever patients may have their susceptibility to pollen lessened by inoculation with dilute extract of pollen; the use of these extracts gives excellent results in a proportion of cases, and, more recently, the attempt has been made to test susceptibility to, and to immunise against, other proteid poisons.

ACCESSORY-SINUS SUPPURATION

Ætiology.—In the large majority of cases infection reaches the accessory sinuses from the nasal cavity, and may result from a simple coryza or from

one of the acute infectious fevers. Influenza is especially liable to produce disease of the sinuses, which may also be caused by measles, scarlet fever, erysipelas, enteric, pneumonia or small-pox. In addition, antral suppuration is caused by infection from the teeth, particularly the second bicuspid and first two molars, whose sockets are in closest proximity to the antral floor. The discharge from one sinus readily enters and infects another, so that disease of several cavities often coexists.

Symptoms and Diagnosis.—If the ostium of a suppurating sinus be occluded the pus is secreted under pressure, and the local symptoms are severe, whereas if the secretion can escape freely there may be no symptoms except discharge. The former class of case has been called "closed" and the latter "open" empyema. The difference between the two is, however, only relative, and many cases are alternating, the severe symptoms being relieved by periodical discharge. As the pressure of the pus in the cavity depends on the rapidity of its secretion, and the degree of occlusion of the ostium by inflammatory swelling, it follows that the closed and open cases correspond generally to acute and chronic suppuration; acute suppuration is usually fairly obvious, but some chronic cases with scanty secretion are only to be detected after very careful examination and may be for long the undiscovered cause of post-nasal catarrh, pharyngitis or chronic toxæmia.

The symptoms, then, are swelling, pain, tenderness and discharge, together with the secondary effects of the suppuration. Swelling is rare; the bony walls are not bulged by an empyema, and this is a point of distinction between it and a tumour or cyst, but occasionally spread of the inflammation causes periostitis, or a fistula in the bone is formed leading to an abscess outside the sinus. Thus, in frontal sinusitis a swelling may appear at the junction of the inner and upper walls of the orbit, displacing the eye downwards and outwards, or an abscess may form here and, after opening, leave a fistula. Similarly, ethmoidal disease may produce a swelling farther back on the inner wall of the orbit, displacing the eyeball outwards. In antral empyema, a little œdema of the cheek, or slight swelling in the canine fossa, may be found, but a swollen cheek is more likely to be due to dental periostitis, while any definite bulging of its bony walls is an indication of a tumour. Pain is often severe in acute cases, and in chronic suppuration there may be considerable neuralgic pain. Pain of an intermittent character, relieved by a sudden gush of discharge from the nose, is highly characteristic of sinus disease, as also is a peculiar periodicity, for it tends to begin regularly at the same time every morning and to get better during the afternoon. The pain may be of a local inflammatory character, or may be of a neuralgic type and referred to various parts. In antral suppuration it is over the cheek, or may be referred to the teeth or frequently to the supra-orbital region. The pain of frontal sinusitis is over the cavity or along the supra-orbital nerve; that of ethmoidal disease is over the nasal bridge, behind the eye or in the temple, and in sphenoidal suppuration, in the middle of the head, behind the eye, on the vertex or in the occipital region. Tenderness can usually be elicited in frontal empyema by percussion over the anterior wall, and especially by pressing upwards against the floor of the cavity; it is less marked in antral disease, in the canine fossa. Discharge into the nose is the most important, and often the only, symptom. A localised stream of pus in the nose, which reappears after removal, is, in the absence of a foreign body, conclusive

evidence of suppuration in an accessory sinus. The differentiation of the affected sinus is made by following the pus to its source with a probe and, in the case of the antrum, by tapping with a trocar and cannula. The antrum, frontal and anterior ethmoidal cells open into the middle meatus, and the posterior ethmoidal and sphenoidal into the superior meatus. Further assistance is afforded by transillumination and skiagraphy. Fetor, both subjective and objective, is often present, and a serious degree of anæmia and ill-health frequently results.

Complications.—These include pharyngitis, laryngitis, bronchitis, and otitis media; the swallowed pus causes various forms of gastric and intestinal disorder, including appendicitis. Acute septicæmia, and pyæmia are rare, but symptoms of chronic poisoning are common, and include anæmia, arthritis, fibrositis, and even mental aberrations. A very important series of complications results from extension of the inflammation to surrounding parts: orbital abscess or cellulitis, osteo-myelitis of the frontal bone, cerebral abscess, thrombosis of the cavernous sinus, paralysis of the oculo-motor nerves and, from the sphenoidal sinus, papillœdema and optic atrophy.

Treatment.—This, in acute cases, consists in rest in bed, hot fomentations to the affected part, aperients, a light diet, and a few doses of aspirin. Inhalations of mentholised steam at frequent intervals are of value, and may be prepared by adding 10 drops of 25 per cent. solution of menthol in spirit to a pint of steaming water in an inhaler. In recent cases of antral suppuration, the cavity should be tapped with trocar and cannula and washed out with a warm saline lotion; this should be repeated daily or every two or three days, according to the severity of the disease, and will effect a cure in a large proportion of cases in an early stage. Frontal sinusitis has a greater tendency to spontaneous cure; the anterior end of the middle turbinal may be amputated and occasionally a cannula can be passed and the cavity washed out. Cases which fail to recover under such treatment, and those of chronic suppuration, must be submitted to operation.

SYPHILIS

Congenital Syphilis

The *early form* appears at any time within 3 months after birth, usually within the first few weeks. The symptoms, frequently called "the snuffles," are those of nasal discharge and obstruction; the former may be thin and ichorous, or purulent and bloodstained, and is often associated with cracks and excoriations about the nostrils, upper lip and angles of the mouth; the obstruction may cause attacks of choking and frequently prevents the baby from taking the breast, and so produces wasting and malnutrition. These symptoms are not pathognomonic of syphilis, but may also be caused by catarrhal and purulent rhinitis, therefore the diagnosis must be established by the concomitant lesions.

The *late form* appears usually about the period of puberty, but may occur at any time after the age of about 5 years. It is characterised by a slow destructive gummatous infiltration and ulceration, and the symptoms are those of nasal catarrh and obstruction, frequently with fetor and crusting;

this chronic rhinitis destroys the ciliated epithelium, and may thus cause a true atrophic rhinitis which persists after the syphilis has become quiescent or cured. Congenital syphilis is apt to produce a very characteristic "saddle-back" flattening of the bridge of the nose.

Acquired Syphilis

Primary chancre is very rarely seen on the ala of the nose, and is accompanied by bubo of the submaxillary and pre-auricular glands, and by much induration and swelling.

Secondary syphilis does not produce noticeable symptoms in the nose; there may be rhinorrhœa and obstruction associated with hyperæmia of the mucosa.

Tertiary syphilis occurs usually in the form of a diffuse gummatous infiltration and ulceration, which may proceed to necrosis of any of the bony or cartilaginous walls of the nose; there is profuse purulent discharge, often bloodstained, which tends to dry into greenish-black crusts, the odour of which is extremely offensive. A localised gumma may occur on the septum, where it forms a smooth round swelling projecting into both nostrils which, by its contraction after healing, produces a steep depression of the bridge just below the nasal bones. Syphilitic ulceration sometimes attacks the external parts of the nose, causing perforation of the ala, or destruction of the columella with a characteristic depression of the nasal tip.

Diagnosis.—This seldom presents much difficulty; the form with crusting and ozæna imitates atrophic rhinitis, but in the latter there is never necrosis or decided ulceration—indeed intranasal necrosis may be considered pathognomonic of syphilis. A septal gumma has an appearance identical with that of a hæmatoma, but without the sudden onset and history of traumatism. Syphilitic perforations nearly always involve the bone, whereas those due to rhinitis sicca or lupus never do. Some cases of diffuse infiltration resemble lupus; but in the latter there is no necrosis or offensive odour, the characteristic nodules are usually to be seen at the edges of the lesion, and other patches of lupus may be found on the skin or in the fauces. The chief difficulty of diagnosis lies between severe syphilitic infiltration and malignant disease, but it can usually be determined by the clinical appearance, especially by the characteristic edge of the syphilitic ulcer, by the examination of an excised portion, by the Wassermann reaction, and by the results of anti-syphilitic treatment.

Treatment.—General treatment must be very prompt and energetic to prevent irremediable deformity, and should ordinarily be begun with the injection of arsphenamine or of one of its congeners. Of local treatment, the lesions should be kept clean by frequent syringing with a saline lotion, to which lysol, sanitas or listerine may be added when the odour is offensive; any necrosed bone must be removed as soon as it is loose.

LUPUS AND TUBERCULOSIS

Ætiology.—With the exception of the rare occurrence of tuberculous ulceration as a terminal infection in advanced phthisis, the lesions produced

in the nose by lupus and by tuberculosis are indistinguishable; it appears that the tubercle bacillus finds in the nasal mucosa a medium unsuitable for its development, its virulence is diminished, and it can only produce the modified lesions known as lupus. It is possible, also, that this modification of the bacillus by sojourn in the nose is the ordinary cause of lupus; at any rate it is frequently primary in the nares, whence it spreads to the fauces and larynx and on to the face and hands. The disease begins most often between the ages of 15 and 30, is twice as common in females as in males, and is usually seen in badly nourished people of the poorer classes.

Symptoms.—The early lesions are found on the antero-inferior part of the septum, the nasal floor and the front end of the inferior turbinal, within reach of the finger-nail, which probably conveys the infection. The characteristic "apple-jelly" nodules are seen, with or without ulceration, the latter with rounded slightly raised margins, and tending to spread in some directions and cicatrise in others. The lesions are covered by small adherent scabs, and perforation of the septal cartilage is common. The alæ often become involved with destruction of the margin or with perforation, and the nostrils may be much narrowed and deformed by scarring, while the lachrymal duct is frequently involved. The progress of the disease is extremely slow and may continue over many years. The subjective symptoms are nasal obstruction with a slight sticky discharge.

Diagnosis.—The nares should be examined in all cases of cutaneous lupus, for, if the disease remain unhealed in the nose, relapses will continually occur. In the majority of cases of nasal lupus the diagnosis is cleared up by the presence of lesions or scars on the face, fauces or larynx. The difficulties of diagnosis are from rhinitis sicca with perforation, and from syphilis. The typical brownish nodules are pathognomonic and can always be found by careful examination when the lesions are progressing; they can be made more conspicuous by blanching the mucosa with adrenaline. The scabbing of rhinitis sicca quickly clears up under simple emollient treatment, while the lesions of syphilis are more rapidly progressive and tend to involve bone.

Treatment.—The affected areas are defined by the application of adrenaline and thoroughly and carefully scraped away with a sharp spoon, a general anæsthetic being employed if the lesions are extensive; small lesions and recurrences are destroyed with the galvano-cautery. Nascent iodine by Pfannenstiel's method may be employed; sodium iodide is given in 7-grain doses six times a day, while the nose is packed with gauze kept moist with peroxide of hydrogen, 10 volume strength, with 5 per cent. of acetic acid added; when a marked reaction has been obtained this solution should be diluted to half its strength, the iodide being continued as before; the treatment may have to be persisted in for several months. Radium is still under trial, and tuberculin has not established its value in this affection.

Of general treatment, arsenic in full doses, fresh air, cod-liver oil and fattening foods are of value. Lupus does not show the same tendency to spontaneous cure in the nose as in the larynx; it is easy to obtain improvement, but complete cure is difficult.

TUMOURS OF NOSE

Papilloma occurs on the skin lining the vestibule and differs in no respect from cutaneous warts elsewhere. On the nasal mucosa it is excessively rare occurs usually on the septum, has a narrow pedicle, a rough red or greyish surface, and bleeds readily when touched; occasionally the growths are multiple and, when large, are difficult to diagnose from a malignant growth, but they do not erode bone; they tend to recur locally after removal.

Fibroma, similar to the naso-pharyngeal fibromata, occurs, though rarely, as a smooth pink growth attached to the posterior region of the nares. It bleeds readily and spontaneously and demands great caution in removal.

Angio-fibroma, or "bleeding polypus of the septum," is less uncommon. It varies from the size of a pin's head to that of a filbert, is red or purple, smooth or finely lobulated, sessile or pedunculated, and grows from the anterior part of the septum. The prominent symptom is epistaxis, for the tumour bleeds freely and spontaneously. When pedunculated, it may be removed with the snare and the base cauterised; when sessile, it should be stripped off the underlying cartilage with an elevator. Recurrence is common.

Osteoma and *enchondroma* are extremely rare, usually grow from the ethmoid region and produce obstruction and deformity.

Cysts.—Mucous polypi are occasionally cystic; the so-called "ethmoidal cyst" is an enlarged cell in the anterior part of the middle turbinal pressing on the septum and causing obstruction and headache. True cysts are sometimes seen on the anterior part of the nasal floor, and arise from the roots of incisor teeth. When small, they may be treated by intranasal removal of part of the wall; when large, they should be dissected out from the gingival fold. *Mucoceles* are cystic dilatations of the antrum, frontal sinus, or an ethmoidal cell.

Malignant tumours occur in all varieties: carcinoma, sarcoma, and endothelioma. Though they sometimes appear on the septum or nasal floor, the usual site of origin is the ethmoidal region. They tend to expand the bones of the face, producing a characteristic frog-like deformity, and they frequently invade the antrum and expand its walls, constituting a common variety of tumour of the upper jaw. The facial, palatine and orbital walls of the antrum may each be bulged outwards, the latter with displacement of the eyeball, and egg-shell crackling can sometimes be elicited. Sanious discharge and free spontaneous hæmorrhage are prominent symptoms and important for diagnosis. Surgical excision produces permanent cure in only a small proportion of cases; better results, especially in endothelioma and sarcoma, are obtained by the implantation of radium. According to the situation of the growth, access is gained by opening the antrum through the canine fossa, by lateral rhinotomy, or for the lower part of the nose by an incision in the gingivo-labial fold from the molar teeth of one side to the other.

HAROLD S. BARWELL.

DISEASES OF THE NASO-PHARYNX

ADENOIDS

Ætiology.—By this term is implied a chronic enlargement of the lymphoid tissue of the naso-pharynx, the "pharyngeal tonsil." This is normally present in childhood and disappears by the age of 20 or thereabouts, but if chronically enlarged may remain up to any age. The precise stage at which the enlargement becomes pathological can only be determined by the symptoms which it produces; these usually become manifest between the ages of 3 and 8, but occasionally show themselves at or soon after birth. The incidence of adenoids is universal, but they are most common in damp temperate climates, and chronic or recurrent nasal catarrh is the principal factor in the causation; the infectious fevers, particularly measles, scarlet fever, and diphtheria, are also a frequent cause of the hypertrophy.

Pathology.—The adenoid, as it should really be called, or enlarged pharyngeal tonsil, is a mass of lymphoid tissue of definite anatomical shape; it is thickest above and tapers away below, and presents a series of ridges which radiate from below upwards and slightly outwards. In older patients the mass is firmer and more fibrous, and the ridges are often adherent in places, leaving deep clefts and furrows in which secretion can collect and decompose.

Symptoms.—The symptoms of adenoids are many and various, and include those due to nasal obstruction, those caused by infection and by the extension of inflammation, and reflex processes attributable to irritation and lowered vitality. In infants the nasal obstruction interferes with sucking and a serious degree of malnutrition will result unless the baby be carefully spoon-fed. Older children snore at night, breathe heavily in the day, and either bolt their food or eat very slowly owing to the necessity of breathing through the mouth. Owing to lack of oxygen the patients sleep restlessly, wake unrefreshed and often suffer from a peculiar inability to concentrate the attention sometimes called "aprosexia." Persistent nasal obstruction during the period of growth mechanically produces permanent deformities of the jaws and face which narrow the nasal passages, prevent the mouth from closing naturally and thus perpetuate mouth-breathing. When the mouth is habitually held open, the alæ nasi are pulled downwards with the cheeks, and become narrow and slit-like and fall in like valves with each inspiration; this "alar collapse" is an important cause of obstruction in neglected cases of adenoids. The palate is narrow and highly arched; the dental arch is narrow and V-shaped, so that the upper incisors, crowded and prominent, look outwards rather than forwards, and are not covered by the short upper lip; the lower jaw retains its infantile obtuse angle, and the lower incisors lie behind the upper; the chin is receding and, in the worst cases, when the molar teeth come into contact on biting, the incisors cannot meet. Only a proportion of cases of adenoids show these deformities, and there is, indeed, considerable uncertainty as to the importance of adenoids in their ætiology; undue softness of the bones, such as occurs in rickets, is doubtless an additional factor, and also in the causation of the malformations of the chest which result from the obstruction to the entry of air. The long

narrow unexpanded chest with acute costal angle and prominent scapulæ is the commonest deformity. Harrison's sulcus, a transverse depression corresponding to the attachment of the diaphragm; pigeon-breast, a prominent sternum with depressed costal cartilages; and funnel-breast, a sharp depression at the lower end of the sternum, are also encountered.

Various infective processes result from the spread of inflammation and, if the naso-pharynx be large, are not necessarily associated with nasal obstruction. The terribly common catarrhal and suppurative affections of the ear in children are, in an overwhelming majority of cases, the result of adenoids. Blepharitis and phlyctenular conjunctivitis are also associated with adenoid vegetations. Feverish attacks, often with tender enlargement of the cervical glands, are caused by infection of the pharyngeal and faucial tonsils, and tuberculous disease of the glands is usually due to passage of the bacilli through these portals; in such cases the tonsils and adenoids may remain unaffected or may themselves show tubercles under the microscope. Chronic or recurrent bronchitis frequently results from the infection spreading to the lower air-passages. The mucus secreted by the adenoids is swallowed in large quantities, and produces derangements of stomach and intestines with failure of growth and general health. Finally, mouth-breathing predisposes to dental caries. The irritation of these vegetations, and their effect on respiration and the general health, account for numerous reflex and nervous disturbances. Among them may be enumerated laryngitis with spasm called "laryngitis stridula," spasm of the glottis without laryngitis or "laryngismus stridulus," stammering, reflex cough, asthma, night terrors and nocturnal enuresis; it should be stated that the latter disorder is by no means always to be cured by removal of the concomitant adenoids, and that in general too much stress must not be laid upon the presence of adenoids as the causative factor in all these reflex disturbances.

Diagnosis.—In the majority of tractable children a view of the naso-pharynx can with patience be obtained with a good light and a very small rhinoscopic mirror, when the upper part of the septum and the concavity above it are seen to be occupied by an irregular convex mass. Where this is impossible a rapid digital examination may be required; this is extremely unpleasant to the little patient, and may be postponed, in those cases where the tonsils are sufficiently large to call for removal, until the child is anæsthetised. Similarly, in very frightened, intractable children, if the symptoms point strongly to adenoids it is wiser to give an anæsthetic for examination, being prepared to remove the vegetations if present. In the mongolian type of idiocy the tongue is large and the mouth persistently open, and in microcephaly the extremely undeveloped naso-pharynx causes nasal obstruction; cases of both these types of maldevelopment are often brought to the doctor in the hope that removal of their adenoids will cure their "backwardness," and care should be taken not to fall into the error of performing a useless operation, though if a well-marked adenoid be present it should be removed under a guarded prognosis. On the other hand, adenoids can be present and produce serious secondary effects without causing nasal obstruction or any appearance of the typical "adenoid facies."

Treatment.—The normal naso-pharyngeal tonsil becomes swollen during a coryza, and such temporary swelling should not be diagnosed as "adenoids," by which term chronic hypertrophy is understood, and does not call for

removal provided that it subsides promptly, does not frequently recur, and is not associated with otitis media or other important complications. In such cases, and when the only symptom is a mild catarrh, the regular use of a simple warm saline lotion with a rubber ball-syringe (see p. 1086) will often effect a cure; in children below the age of 5 or 6 syringing is apt to be difficult and the lotion may be used in a spray, while in infants it is best to drop it into the nostrils from a small pipette like the filler of a fountain-pen. This treatment should be combined with open air—if possible a change to the seaside or a bracing country district—cod-liver oil, iodide of iron, or arsenic. Breathing exercises are of great value in these slight catarrhal cases, but only do harm where there is marked obstruction.

When the enlargement frequently recurs or has gone on to chronic hypertrophy, operative removal is the only treatment, and this is especially called for when any aural symptoms supervene, or when cervical adenitis is present. After operation the general treatment referred to above is valuable, but the nose should on no account be syringed until healing is complete, as this encourages aural complications. If the alæ nasi are collapsing, or the chest narrow, breathing exercises are of use, but healthy open-air occupations are more useful still. In patients in their teens, or upwards, turbinal hypertrophy has not infrequently resulted; the surgeon should be prepared to snare off enlarged posterior ends of the inferior turbinals at the time of the operation, and intranasal cauterisation may be required later.

TUMOURS

Innocent tumours in the naso-pharynx are exceedingly rare; the so-called "choanal polypus" is a variety of nasal mucous polypus which hangs into the naso-pharynx from a long pedicle attached within the naris.

Fibroma of the naso-pharynx, or naso-pharyngeal polypus, occurs usually in males between the ages of 10 and 25, grows by a broad pedicle from the periosteum of any part of the walls of the naso-pharynx, usually from the basi-sphenoid, and forms a smooth, rounded, pink mass which fills the naso-pharynx and sends prolongations into the nasal cavities. The palate is pushed downwards, the bones of the face expanded, and the eyeballs separated and displaced, producing the "frog-face" deformity. The cardinal symptoms are nasal obstruction and discharge, with headache and severe epistaxis; aural complications may follow, or the eyes may be involved, with diplopia, exophthalmos and compression of the optic nerve; and, finally, death results from exhaustion, hæmorrhage, sepsis or cerebral invasion. Histologically the tumour is composed of fibrous tissue containing numerous thin-walled blood vessels and a variable admixture of round or fusiform cells, so that in some cases it might be described as a fibro-sarcoma; but it is not truly malignant, for it neither involves the glands nor becomes disseminated, though there is a tendency to local recurrence after removal.

Radium has proved of considerable value in reducing the size and vascularity of these growths, as a preliminary to operation.

Malignant tumours are not common in the naso-pharynx, but epithelioma, sarcoma and endothelioma all occur. The early symptoms are chiefly pains of a neuralgic character and those produced by Eustachian obstruction;

later, epistaxis, nasal obstruction, secondary involvement of glands and affections of the eye and cranial cavity may appear. Surgical removal is rarely feasible, but sarcomata and endotheliomata in this region sometimes yield remarkably to treatment by radium.

HAROLD S. BARWELL.

DISEASES OF THE LARYNX

ACUTE CATARRHAL LARYNGITIS

Ætiology.—The affection ordinarily occurs as part of a coryza, or cold, the inflammation spreading downwards from the nose or naso-pharynx. It is also caused by over-use of the voice, especially with faulty voice-production, and frequently a slight catarrh is made worse by using the voice during a cold. It occurs in many infectious fevers, *e.g.* influenza, measles, scarlet fever, typhoid and small-pox, and it is occasionally a result of traumatism, instrumentation, or the inhalation of irritating fumes in chemical works or of the gases used in warfar. Predisposing causes are chiefly those factors which favour attacks of coryza, such as nasal obstruction or discharge, sedentary occupations and overheated rooms; apart from local tuberculous lesions, consumptives are very subject to laryngeal catarrh.

Symptoms.—The symptoms consist of hoarseness or aphonia, local discomfort varying from dryness or tickling to a burning sensation or actual pain, and irritable cough. There is little expectoration, unless the trachea and bronchi are involved. At the onset there may be slight feverishness and malaise. The degree of hoarseness is by no means proportionate to the objective appearances; the voice may be quite good in cases of decided hyperæmia, and may be completely lost when little abnormal is to be seen. This depends largely on the neuro-muscular tone; a muscular man will retain a strong voice with a degree of inflammation which would render a weakly woman completely aphonic—indeed some women lose the voice with every slight cold, so that it becomes difficult to differentiate between laryngeal catarrh and "functional aphonia." On the other hand, in some voice-users redness of the cords appears to be the normal condition and causes no interference with function. This variable effect on the voice is to be observed in all forms of laryngeal disease. In children, acute laryngitis is a serious affection. They show a far greater tendency to œdema and to spasm, and as the glottis is not only absolutely but relatively smaller than in adults, a dangerous dyspnœa may ensue with great rapidity. The larynx is reddened, and this is most obvious on the parts usually pale—the epiglottis and vocal cords, the vessels on the former being unduly prominent. The cords may be red, pink, yellowish, or merely have lost their bright pearly lustre. A small amount of mucous secretion is generally present, but no large accumulations or strings of mucus, such as are seen in chronic laryngitis. There is often a little swelling of the cords so that, on phonation, their edges come into contact at the centre; this explains how singers' nodules are caused by use of the voice during a laryngitis.

Treatment.—People suffering from the slighter degrees of laryngitis

rarely apply for treatment, unless they are professional voice-users. The patient should remain in a warm (65° F.), well-ventilated room, preferably in bed, and must not attempt to use the voice. The coryza, if present, should be treated at the same time. Steam inhalations are of value and may be used from an inhaler or from a jug round the mouth of which a towel has been wrapped in the shape of a cone. The water should be at a temperature of 130° to 140° F., and one of the following medicaments may be added in the proportion of one drachm to the pint: Compound tincture of benzoin (Friar's balsam) fl. oz. 1, with or without menthol, grs. 10–15; or benzoic acid, grs. 3, kaolin, grs. 12, tincture of tolu, min. 18, and water to fl. oz. 1, these being sedative, while oleum pini sylvestris, min. 40, magnesii carb. levis, grs. 20, water to fl. oz. 1 is mildly stimulating. Steam inhalations should only be ordered when the patient can remain in a warm room; when he is not confined to the house, or in a later stage, an oily solution from an atomiser is preferable, such as menthol, grs. 7, camphor, grs. 3, chlorbutol, grs. 5, liquid paraffin, fl. oz. 1. Internally, expectorants are indicated; tincturæ ipecacuanhæ, min. 10, or vinum antimoniale, min. 5, potassium iodide, grs. 2 or 3, ammonium carbonate, gr. 4—singly or in combination—or ammonium chloride, grs. 5, or oil of cubebs, min. 5 in syrup, every 4 or 6 hours. If cough is severe it should be restrained; a lozenge of morphine and ipecacuanha is useful, or a linctus containing diamorphine hydrochloride, gr. $\frac{1}{24}$, or liquor morphinæ, min. 2 to 4 to each drachm.

The acute laryngitis of children calls for prompt treatment. One or two grains of calomel may be given every 3 hours until the bowels have acted freely, after which it may be continued in $\frac{1}{2}$-gr. doses three times a day. Hot fomentations to the neck and a steam-kettle are advisable, and in acute febrile cases, 1 minim each of tincture of aconite and vinum antimoniale every 3 hours. If dyspnœa occurs, an emetic dose of ipecacuanha often gives prompt relief; 60 minims of the tincture followed by 30 minim doses every half-hour until vomiting occurs: in very young or weakly children, 15 minims every quarter-hour is to be preferred.

SPASMODIC LARYNGITIS

Synonym.—Laryngitis Stridula.

This is simply catarrhal laryngitis with spasm of the glottis as a marked feature. It is a disease of childhood and is predisposed to by general ill-health, rickets and adenoids. The onset is that of an ordinary cold, with slight feverishness, hoarseness and a frequent cough, and during the evening or night the respiration becomes embarrassed. There is inspiratory stridor, recession of the epigastrium and lower ribs and, in some cases, an alarming degree of asphyxia. The symptoms tend to subside towards morning and, though they may recur on the next few nights, it is usually with diminishing severity. The condition should be distinguished from laryngismus stridulus, in which there is no hoarseness or other symptoms between the attacks. The evanescence of the symptoms serves to distinguish it from œdematous laryngitis and from diphtheria, in which the attacks become increasingly severe. The general health requires attention, and adenoids, if present, must be removed after recovery has taken place.

ŒDEMATOUS LARYNGITIS

Synonym.—Œdema of the Larynx.

Ætiology.—Œdema of the larynx is not a disease but a pathological condition due to a variety of causes. Non-inflammatory œdema may be mentioned here for the sake of completeness; it occurs, though rarely, as part of the general anasarca of renal and cardiac disease. Angio-neurotic œdema sometimes occurs in the larynx, in which event it produces rapid and sometimes fatal dyspnœa (see p. 1074). The swelling which occasionally results from administration of potassium iodide in susceptible subjects may be placed in the same category.

Inflammatory œdema seldom results in adults from a simple catarrh, but it may do so in children; it more often occurs as part of an acute septic infection of the pharynx, trachea and bronchi, "acute fulminating laryngo-tracheo-bronchitis." Œdema may follow various forms of traumatism, the drinking of corrosive poisons, inhalation of irritating vapours, such as the poison gases of warfare, the lodgment of foreign bodies, or rough or unduly prolonged bronchoscopy. Scalding, from attempts to drink from a kettle-spout, is a common cause among children. In other cases it is a sequela of typhoid fever, pneumonia, scarlet fever or small-pox, and is a local complication of syphilitic, tuberculous, cancerous or traumatic ulceration.

Symptoms.—If part of a septic pharyngo-laryngitis, the general symptoms are severe. The chief local symptom is dyspnœa with inspiratory stridor and the associated symptoms of asphyxiation; there is hoarseness or aphonia, local discomfort and tenderness, and sometimes dysphagia. The arytenoepiglottidean folds are enormously swollen, appearing as pale or purple translucent flask-shaped masses; if the epiglottis be œdematous it forms a sausage-shaped swelling of the same appearance. The mucosa of the vocal cords is too adherent to permit much swelling, and "œdema of the glottis" is therefore a misnomer. The subglottic region is lax and may become swollen; indeed, the œdema may be confined to this region and then appears as a red swelling below each vocal cord. In children œdema may be inferred from the steadily increasing dyspnœa without the rapid increase and decrease typical of spasmodic laryngitis.

Treatment.—In slight cases, the swelling may be reduced by sucking ice and by the application of an ice-bag to the neck; the latter is inadmissible in young children. A spray of adrenaline, 1 in 1000, may be used. Hypodermic injections of pilocarpine, gr. $\frac{1}{8}$, are recommended and, for the œdema produced by iodides, large doses of bicarbonate of soda. Free scarification of the œdematous tissues at the upper aperture should be practised without undue delay; in adults this should be done with a laryngeal lancet under guidance of the mirror, but in children it is best performed with a curved bistoury guarded to near the point with strapping and passed down along the left forefinger as a guide. If this does not give quick relief, or if the dyspnœa be severe, tracheotomy should be performed without delay. Intubation is not suitable for cases of œdema of the upper aperture of the larynx, though it may be employed for subglottic cases, provided that skilled attention be immediately available should the tube be coughed out. Angio-neurotic œdema should be treated by a spray of adrenaline, and the same

drug, or a colloidal preparation of calcium, may be injected hypodermically; tracheotomy may here also be required.

MEMBRANOUS LARYNGITIS

The formation of false membrane in the larynx is nearly always part of an attack of diphtheria, which is discussed elsewhere, but by the term "membranous laryngitis" is implied a formation of membrane of non-diphtheritic origin. Apart from traumatic cases, due to irritating chemicals and scalds, inflammation of the larynx accompanied by membrane may be caused by streptococcal infection. The affection occurs especially in children between the ages of 2 and 8 years. The first symptom is hoarseness, soon followed by a brassy cough and the signs of dyspnœa; the patient is restless and the temperature rises rapidly to 103° or 104°. In some cases, however, the disease takes a subacute form, the attacks of dyspnœa being worse at night and abating towards morning. The diagnosis from diphtheria is only possible by bacteriological examination, and pending the report the case should be treated with antitoxin; but it may be noted that the pharynx is nearly always involved in diphtheria, whereas in membranous laryngitis the disease is often primary in the larynx. The prognosis is grave, worse than that of diphtheria since the introduction of antitoxin. An emetic dose of ipecacuanha should be given, and a steam-tent and hot fomentations to the neck are advisable. Calomel treatment is recommended; 1 or 2 grains every 3 hours until the bowels have acted freely, and subsequently 1 grain three or four times a day; the sulphanilamide group of drugs will doubtless be of value in this, as in other streptococcal infections. Tracheotomy or intubation must not be delayed when there is serious dyspnœa.

CROUP

Croup is an expression which dates from a period when the diagnosis of diseases of the throat was less exact than now but, as it is still in occasional use, it may well receive a definition in this place. The term can be used to cover any respiratory obstruction or obstructive dyspnœa, especially in children, but is usually limited to acute affections and therefore does not ordinarily include such conditions as multiple papillomata, congenital web or cicatricial stenosis. Croup may thus be caused by various inflammatory affections such as œdematous laryngitis, membranous laryngitis (both diphtheritic and non-diphtheritic), spasmodic laryngitis and retropharyngeal abscess, or by such reflex disturbances as laryngismus stridulus and spasm of the glottis, and is in fact descriptive of a symptom rather than of a disease.

CHRONIC LARYNGITIS

Ætiology.—The causation is similar to that of acute catarrhal laryngitis; indeed, chronic laryngitis is often the result of recurrent or persistent acute catarrh. The principal factors which predispose to chronicity are nasal

obstructions and discharges, dusty occupations and lack of fresh air, over-use of the voice and faulty voice-production, and the abuse of alcohol or tobacco; consumptives are particularly liable to non-specific catarrhal laryngitis, and oral sepsis must not be omitted. Almost any cause of general ill-health may be included among the predisposing causes, such as gout, rheumatism, anæmia, and gastro-intestinal, cardiac and hepatic disorders.

Symptoms.—The only constant symptom is impairment of the voice, which is hoarse, easily tired or even, though rarely, completely aphonic; it is sometimes weakest when tired in the evening, but is often at its worst on rising in the morning or after a rest. There is frequently a sensation of aching, dryness, tickling or of a lump in the throat, and there is usually some cough, but little expectoration unless the trachea and bronchi are involved.

The objective appearances vary with the severity of the affection. The larynx generally is of a deeper red than usual, and the vocal cords have lost their normal pearly lustre and are pink or grey; they are usually somewhat thickened at the edges, and enlarged vessels may be visible on their surface; the vocal processes are often prominent and may be reddened or show up white against the hyperæmic cord. Strings of sticky secretion may stretch between the cords, or a little globule of mucus may form on the centre of the cord during phonation; adduction is frequently imperfect. When the epiglottis is reddened, its yellow edge stands out clearly and enlarged vessels are visible; the ventricular bands are often swollen so as to hide the outer part of the cords. The mucous membrane in the inter-arytenoid space, thickened and relaxed, is seen to be thrown into folds on adduction of the cords, and may form a mass large enough to prevent their approximation.

Atrophic rhinitis usually produces a form of inflammation, *laryngitis sicca*, in which small brown scabs adhere to the cords and posterior commissure, but occasionally the disease itself spreads to the larynx, which is covered by large greenish or brownish-black fetid crusts; more rarely still the crusts extend into the trachea and cause severe dyspnœa, which may prove fatal.

Pachydermia laryngis is a somewhat rare variety of chronic laryngitis, occurring principally in middle-aged men. It is frequently ascribed to alcoholism, perhaps on insufficient grounds, to syphilis and to tubercle; the diagnosis between pachydermia and these two diseases is, however, often a matter of difficulty. The characteristic epithelial thickenings are probably of the nature of corns, resulting from frequent cough and continued irritation. There is hoarseness of a rough raucous character, but no particular discomfort. The epithelial thickening is pink or whitish and occupies the posterior or cartilaginous region of the glottis from the vocal processes backwards to the posterior commissure. A circumscribed swelling appears on each vocal process, with a small cup or depression at the apex; the approximation of the cords is better than would be expected, because the prominence on one vocal process fits into the depression at the other. The epithelium of the inter-arytenoid space is thrown into ridges, which fill up the angles between the arytenoid and the posterior commissure, but leave a depression in the middle line. These firm, opaque, symmetrical swellings, without ulceration, are distinguishable from the soft irregular granulations

of a tuberculous lesion, and the cup-shaped swelling on the vocal process, even when more marked on one side, should not be mistaken for an early epithelioma.

Treatment.—The detection and correction of the ætiological factors are the most important part of treatment. Any constitutional disturbance, such as anæmia, rheumatism, gout or dyspepsia, should receive attention. Over-indulgence in tobacco or alcohol, lack of ventilation and exposure to dust must be considered, and with teachers the black-board chalk is a common source of irritation.

Incorrect voice-production is a factor of great importance especially, but by no means exclusively, among those who use the voice largely in their occupations; in such, a course of lessons in voice-production often works wonders. In a large proportion of cases the primary cause of the laryngitis is to be found in the nose, therefore any source of nasal obstruction, catarrh or suppuration must be carefully looked for and treated; any concomitant pharyngitis should also receive attention.

Locally, treatment must begin with rest of the voice, which should be absolute in the case of professional voice-users. Where there is much secretion a saline lotion may be used in a spray—sodium bicarbonate, borax, sodium chloride, 10 grains of each, thymol water, 120 minims, glycerin, 60 minims, water to 1 ounce. Oily solutions are usually preferred, such as menthol, 5 grains, camphor, 2 grains, chlorbutol, 5 grains, or oil of eucalyptus, pine or gaultheria in similar proportions, to an ounce of liquid paraffin. The direct application of pigments is not often called for, and is to be recommended only when pachydermatous changes are present; in such cases the cautious application of a solution of nitrate of silver on a cotton-wool mop once a week may be tried, beginning with 5 grains to the ounce and increasing the strength gradually to 50 or more grains. Dundas Grant advises an alcoholic solution of salicylic acid, beginning with 1 per cent. and increasing to 6 or 8 per cent.

Internally, small doses of potassium iodide, 2 or 3 grains, or the yellow proto-iodide of mercury, $\frac{1}{10}$ grain, three times a day over long periods, is of value.

CONGENITAL LARYNGEAL STRIDOR

In this condition there is an exaggeration of the infantile shape of the upper aperture of the larynx; the epiglottis is sharply folded laterally, the ary-epiglottic folds are almost in contact, and the opening is thus reduced to a narrow vertical slit. As these parts are very flaccid in infancy, they become sucked together during inspiration and, by their vibration, produce the characteristic stridor. This stridor is noticed very soon after birth, it is inspiratory, of a peculiar purring or even musical character, and is most marked during active breathing and crying. The voice is unaffected, and there is remarkably little sign of dyspnœa or distress. These characteristics distinguish the condition from other forms of obstruction found in infants, such as laryngeal webs or papillomata, or "thymic asthma." It tends to disappear during the second year of life, but the prognosis must be guarded in early infancy, for an attack of bronchitis is more than ordinarily dangerous and kills a proportion of these patients.

SYPHILIS

Congenital Syphilis

The early, or secondary, form appears in the first few months of life and is rarely recognised, but it may be suspected when the cry is hoarse in an infant with active syphilitic lesions.

Tertiary lesions are rare, and usually make their appearance about puberty, less often during the second dentition. The disease takes the form of diffuse infiltration with or without ulceration; the swelling may produce obstruction, and rarely cicatricial stenosis may ensue. The symptoms are stridor with hoarseness, and tracheotomy may be required.

Acquired Syphilis

Symptoms.—Secondary lesions are superficial, cause no symptoms but hoarseness, and seldom come under observation. The commonest manifestation is an erythema which differs from that of catarrhal laryngitis by being more uneven and patchy in its distribution, and may affect one cord, leaving the other normal. Mucous patches are occasionally found on the cords or on any part of the larynx, appearing as superficial erosions with a smooth greyish base and a sharply defined hyperæmic margin. The fauces are nearly always affected at the same time.

Of tertiary lesions, the superficial serpiginous ulcer is occasionally seen with the same characters with which it more commonly appears on the fauces. Diffuse infiltration may attack any part of the larynx, but chiefly, in contra-distinction to tuberculosis, the anterior regions, such as the epiglottis and the front parts of the vocal cords. Subglottic infiltration is fairly frequent and abduction of the cords often limited, so that stenosis is much commoner than in tuberculous disease. The typical circumscribed gumma is distinctly rare; it is single, unilateral, and attacks especially the epiglottis and arytenoids, and usually breaks down rapidly to form a deep excavated ulcer, which may result in perichondritis, exfoliation of cartilage, and, ultimately, in severe cicatricial stenosis. The subjective symptoms are hoarseness, of a peculiar rough "raucous" character, and sometimes dyspnœa with stridor; pain is in general not a prominent symptom, but a gumma on the upper aperture may cause severe dysphagia.

Diagnosis.—From tuberculous disease the diagnosis is discussed under that heading (see p. 1107). From epithelioma a gumma is distinguished by its more rapid evolution; the edge of an epithelioma is thick and everted and its base nodular, whereas these characters are less marked in syphilitic ulceration, the margin of which is hyperæmic and frequently sharply cut; while other parts of the larynx or fauces often show syphilitic lesions. The hard infiltration of secondarily involved glands is characteristic of malignant disease.

Treatment.—General treatment is urgently called for to prevent perichondritis and stenosis. Local treatment is not often required. Tracheotomy should be performed when decided dyspnœa is present; it seems to aid the recovery of the larynx, and the tube can often be omitted in a short

time, when anti-syphilitic medication has removed the obstructing lesion. Necrosed pieces of cartilage must be removed by internal or external operation, and insufflations of orthoform are indicated when dysphagia is present.

LUPUS

Lupus in the larynx is comparatively rare, and is probably always secondary to the disease in the nasal passages.

Symptoms.—The lesions begin on the epiglottis and slowly spread along the aryteno-epiglottic folds; the interior of the larynx is less often attacked and the cords usually escape. The infiltration is composed of tiny red nodules, which develop the typical "apple-jelly" centre and break down to form multiple coalescent shallow ulcers, the smooth base covered by a scanty secretion and with indefinite uninflamed margins. Cicatricial contraction goes on during the progress of the affection, and the epiglottis, if not destroyed, is usually much deformed; but the scars are less thick, and the contraction less severe than in syphilis, and marked stenosis is less common.

Treatment.—The disease shows a decided tendency to spontaneous cure, and in many cases of cutaneous lupus the scars of healed disease can be seen in the larynx. Open-air treatment, as carried out in a sanatorium, with good food, moderate exercise, and cod-liver oil suffices to cure most cases. Arsenic, in large doses, appears to have a specific effect, starting with 5 minims of liquor arsenicalis 3 times a day and increasing the dose gradually to 15 or more minims. Local treatment should be reserved for those cases which general measures fail to cure. If the lesions are confined to the epiglottis, this may be removed; for more diffuse infiltration repeated galvanocautery puncture gives the best results, but over-zealous application will promote stenosis. Good results have been reported from the use of radium, applied externally to the neck in the form of plates.

TUBERCULOSIS

Ætiology.—Primary tuberculosis of the larynx is so rare as to be of no practical importance; in the overwhelming majority of cases the disease is secondary to pulmonary tuberculosis, of which it is a common and important complication. It is probably caused by infection from the sputum, is two or three times commoner in men than in women, and is most frequent between the ages of 20 and 40. St Clair Thomson finds that the difference in sex-incidence is occupational, and that women working in office and factory are as susceptible as men.

Symptoms.—The disease attacks, in order of frequency, the vocal cords, arytenoid region, inter-arytenoid space, ventricular bands and epiglottis; in general the lumen is invaded before the upper aperture, and the posterior rather than the anterior parts of the larynx. The typical infiltration is finely nodular, pallid and soft in appearance; ulcers are shallow, with a smooth speckly base and pale ill-defined margin. On the vocal cord the disease chiefly attacks the posterior half and especially the vocal process, where ulceration readily reaches the underlying cartilage and may produce a deep

triangular excavation. Thickening in the inter-arytenoid region is common; infiltration of the arytenoids results in typical pale semi-translucent flask-shaped swellings, while the epiglottis appears as a firmer red sausage-shaped mass.

Of subjective symptoms, the hoarseness is very characteristic, the voice being weak and effortless and very different from the raucous voice of syphilis. Cough and expectoration are mostly due to the pulmonary disease and not in any considerable degree to the larynx. Pain on swallowing is common and often very intense; there may also be actual obstruction to deglutition and, in a late stage, entry of food into the larynx. Dyspnœa is rare.

Diagnosis.—Although signs of pulmonary tuberculosis are helpful in diagnosis, it is obvious that any kind of laryngeal disease may occur in a consumptive patient.

From simple laryngitis.—In the earliest stage of invasion tuberculous laryngitis may exactly resemble catarrh, but redness of one cord only is certainly not due to catarrh, and the latter quickly improves under treatment. The swollen arytenoids of œdematous laryngitis are less pale and more transparent, while the affection is acute and the entire larynx inflamed. Inter-arytenoid infiltration resembles pachydermia, but the latter is opaquely white, firm and symmetrical.

From lupus, typical tuberculosis differs completely. The former is painless, affects first the epiglottis and upper aperture, is never accompanied by œdema, and tends to cicatrisation. But there is a chronic "lupoid" form of tuberculous laryngitis which attacks the epiglottis and is very similar to lupus.

From syphilis.—The tuberculous ulcer has an ill-defined margin without surrounding hyperæmia; the base has a yellow speckled appearance, and on healing there is little scarring or contraction. The superficial syphilitic ulcer has a well-defined hyperæmic margin, with a smooth, flat base; the deep ulcer is "crateriform," with thickened punched-out edge, and, on healing, leaves a dense scar and marked deformity. In general, syphilitic lesions attack the anterior half of the larynx, tuberculous the posterior; the former look firm and dense, the latter soft, translucent and ill-defined.

From neoplasms.—Only the rare tuberculomata resemble innocent tumours. Occasionally tuberculosis attacks one vocal cord in an elderly patient, and may then easily be mistaken for epithelioma (see p. 1111).

Prognosis.—Any tuberculous lesion of the larynx renders the prognosis of a case of pulmonary tuberculosis much more serious. A considerable number of the superficial lesions become healed; but it is doubtful if any cases of extensive infiltration recover, with the exception of a few rare instances where it is confined to the epiglottis and can be entirely removed.

Treatment.—Tuberculous laryngitis is but a complication of pulmonary tuberculosis, and by far the most important part of the treatment is that of the general infection. For the laryngeal lesions the most valuable remedy is complete silence, but it is a severe and depressing measure and should not be insisted on unless there is a prospect of cure; the pain and irritation

in advanced cases are, however, often relieved by vocal rest. Any concomitant catarrh should receive attention; an oily spray containing menthol and chlorbutol (7 grains of each in an ounce of liquid paraffin) is valuable, and irritable cough should be relieved by a simple lozenge, or, if severe, by heroin, $\frac{1}{12}$ gr. or less in a lozenge or linctus. Attempts to cure by active local treatment must only be made when the pulmonary lesions are quiescent or progressing towards arrest, the general health good, and the local lesions not very extensive. Of these methods the galvano-cautery is the most generally useful, and may be employed to the surface of superficial ulcers, or as multiple puncture of infiltrated areas. Chemical caustics may be applied to ulcerated surfaces, especially on the cords and posterior commissure; lactic acid, 50 to 80 per cent., may be used, or Lake's mixture of lactic acid 50 per cent., formalin 7 per cent., and phenol 10 per cent. Ulcers covered with sprouting granulations may be curetted, and occasionally infiltration of the epiglottis or arytenoid may be removed with punch-forceps.

In advanced cases the dysphagia is so distressing that its relief is of great importance. For this purpose the most valuable drug is orthocaine (orthoform), which may be combined in equal proportions with benzocaine (anæsthesine); it is an insoluble non-toxic powder and is used as an insufflation in doses of 3 to 5 grains half an hour before meals; patients readily learn to inhale it into the throat through a glass tube. Cocaine and morphine should be reserved to the last stages. When the dysphagia is due to infiltration of the epiglottis, the greatest relief is afforded by its removal under cocaine with special punch-forceps; and when the pain is caused by a tense swollen arytenoid, the removal of a piece with punch-forceps relieves tension and gives similar relief. Injection of alcohol into the superior laryngeal nerve is a useful method of alleviating pain in cases of extensive disease. Tracheotomy is seldom required, and tuberculous infection of the wound is common after this operation.

TUMOURS

Innocent Tumours

Singer's nodules are inflammatory epithelial thickenings, and may be considered as a form of pachydermia. They are found in teachers and speakers, rather than in singers, and are caused by faulty voice-production and, especially, by forcing the voice when the cords are inflamed. The appearance is that of a minute pink or whitish nodule on the edge or upper surface of the vocal cord, surrounded by a varying amount of injection; there is usually a nodule symmetrically placed on each cord, but it is frequently larger on one side than on the other. The place where the growth occurs, and which is also the "seat of election" for other innocent tumours, is at the junction of the anterior and middle thirds of the glottis, that is, in the centre of the true vocal cord, for the posterior third of the glottis is cartilaginous. It is here that the cord, if swollen, comes into contact with its fellow on phonation.

Fibromata occur usually on the vocal cord on the same site as the singer's nodule, of which they are in some cases probably a development; or at the

anterior commissure. They are pedunculated, smooth and round, white, pink, or brown from extravasation of blood, and vary from the size of a pin's head to that of a bean. These growths not infrequently become œdematous, when they appear translucent like a nasal polypus, and have been incorrectly described as *myxomata*.

Papillomata are reddish, papillary, pedunculated growths, and occur anywhere on the larynx, but, when single, generally occupy the "seat of election" on the vocal cord, and are seldom found on the posterior half of the glottis. Multiple papillomata occur especially in childhood and, as they present special characteristics, will be considered separately later.

Cysts.—A fibroma may degenerate with the formation of a cystic space in its interior. Apart from this, cysts, which may reach a large size, are found as a rarity on the upper aperture of the larynx, especially on the anterior surface of the epiglottis. They are thin-walled and translucent, with ramifying vessels running over the surface.

Angiomata occur, though rarely, on any part of the larynx either as a flat patch or a raised purple mass resembling a blackberry.

All innocent neoplasms are rather uncommon; in addition to those already mentioned, *lipomata, chondromata* and *thyroid-gland tumours* have been observed.

Symptoms.—A tiny growth situated on the vocal cords, or in such a situation as to prevent their approximation, causes hoarseness and a variable amount of aching and discomfort, but even a large tumour elsewhere may cause no symptoms to attract attention. Dyspnœa results in rare cases when a neoplasm is large enough to block the air-way, but it is astonishing how slight a disturbance may be produced by a large tumour if it has grown slowly; inspiration is more difficult than expiration, except when the tumour lies below the glottis. Angiomata cause hæmorrhage, which may be very severe.

Diagnosis.—This is usually easy on inspection, but a growth on the anterior commissure, or one that drops down below the cords, may be readily overlooked. The rare tuberculoma may so exactly imitate an innocent neoplasm as to be only recognisable under the microscope. The important matter of diagnosis from a malignant neoplasm will be referred to under the latter disease.

Treatment.—Tumours situated away from the glottis and causing no symptoms should be left alone. Cysts are treated by making a large hole with punch-forceps or the cautery, for they refill after simple incision. Angiomata, especially if diffuse, are best left untouched, unless bleeding calls for interference, in which case it can usually be checked by the cautery at dull-red heat; diathermy puncture with a fine terminal through a direct laryngeal spatula, or by suspension-laryngoscopy, is a preferable method; if repeated hæmorrhage becomes a danger, the angioma can be excised by an external operation, but is usually more widely spread than appears on laryngoscopic examination. Singer's nodules, if quite small and sessile, frequently disappear under prolonged rest of the voice; the smaller nodules may be lightly touched with the galvano-cautery; larger ones should be removed with forceps. Fibromata and papillomata are removed with forceps; it causes less disturbance to the patient if this be done under cocaine anæsthesia by the "indirect method," *i.e.* under guidance with the laryngeal mirror

provided that the operator has acquired the necessary skill, but since the introduction of the "direct method" they are usually removed through the tube-spatula. After the little operation, absolute rest of the voice should be enjoined for a few days; in cases of singer's nodule a longer rest is necessary, with training in voice-production and avoidance of dust and conditions of vocal strain.

Multiple papillomata.—This rare but serious condition occurs almost exclusively in children and generally attracts attention between the ages of 2 and 4. The warts may be very numerous, fill the lumen with a cauliflower-like mass, and extend to the subglottic region, down the trachea and sometimes on to the pharynx. The first symptom is hoarseness, and long-continued hoarseness in a child should suggest the possibility of papilloma; dyspnœa ensues later and becomes gradually more severe until tracheotomy is necessary. The growths may disappear after tracheotomy, or spontaneously, or after an acute illness, and tend to vanish or cease to recur about puberty. The growths should be removed through the tube-spatula, or by suspension-laryngoscopy, under general anæsthesia; a preliminary tracheotomy is advisable if there is much dyspnœa; several sittings may be required, and the operation must be repeated as often as the growths recur.

Malignant Tumours

Ætiology and Pathology.—Epithelioma is by far the commonest malignant growth in the larynx, but spheroidal-cell carcinoma and sarcoma also occur. Malignant disease of the larynx proper is rare below the age of 40, and is seldom seen in women; but there is a post-cricoid epithelioma, originating on the mucous membrane of the pharynx, which is relatively common in women, and has been known to occur at such an early age as 23. Secondary or metastatic growths are practically unknown in the larynx; on the other hand, owing to the fact that the laryngeal lymphatics do not anastomose freely with other systems, cancers confined to the lumen of the larynx rarely become disseminated and do not readily infect the glands. Therefore, Krishaber's classification into *intrinsic* and *extrinsic* is valuable for treatment and prognosis; the former are those situated within the cavity of the larynx, while the latter affect the upper aperture, epiglottis, arytenoids, and the outer walls.

Symptoms.—Unfortunately, intrinsic malignant tumours do not cause severe symptoms at an early stage and, particularly in hospital practice, frequently do not present themselves for treatment until they have become extrinsic by extension; hence the importance of a laryngeal examination in all patients over 40 with hoarseness which does not rapidly yield to treatment. Hoarseness is the most general, and usually the only, early symptom; owing to the deep infiltration characteristic of malignant disease, it is often more marked than the size of the tumour would appear to warrant. Cough is not a common symptom. Pain is absent in the early stages of intrinsic cancer, but is severe in the later stages and in the extrinsic forms; it radiates to the ear and side of the head, and is made worse by swallowing, speaking and coughing. The later symptoms include involvement of the glands, fetor of the breath, salivation, hæmorrhage, dyspnœa, dysphagia and general cachexia; often the patient dies of septic pneumonia.

On a vocal cord, epithelioma may appear as a definite tumour resembling a papilloma or angioma, or it may begin as a diffuse infiltration, or merely as a localised area of thickening and congestion. On the ventricular band or posterior commissure it usually shows itself as an irregular papillary dusky-red swelling; cancer of the epiglottis ulcerates early and appears as a dirty white or reddish tumefaction. Often the only sign of a post-cricoid growth is a swollen and fixed arytenoid, or merely a pool of saliva in the pyriform fossa; sometimes the upper edge of the growth is visible, but it may be necessary to pass a tube-spatula, or to pull the larynx forward with a probe passed down to the glottis, before it can be seen.

Diagnosis.—In the earliest stage the diagnosis obviously is a matter of extreme importance and sometimes one of great difficulty. The unilateral character of the infiltration is ordinarily sufficient to exclude a simple inflammatory lesion; though pachydermia may be more marked on one side, the lesions are bilateral and the smooth cup-shaped swelling on the vocal process is characteristic. The difficulties of diagnosis are generally between an innocent neoplasm on the one hand, and a tuberculous or syphilitic infiltration on the other. A papilloma or a fibroma on a vocal cord should be regarded with suspicion in a man over 40, and especially if, after removal, the site fails to heal promptly. An innocent neoplasm has a fine pedicle, moves freely in the air-current on phonation, there is no tumefaction at its site of origin, and it is found at or in front of the middle of the vocal cord. A malignant growth may occur in any situation; it is less movable and pedunculated, the cord in the neighbourhood is frequently swollen and may show a leash of tiny vessels running to the tumour; a white spiky appearance of the papillæ is suggestive of malignancy; a sluggish delayed movement of the cord is an important sign, insisted on by Semon, but its absence by no means excludes malignancy, for it only occurs when the growth has infiltrated the muscles, and its presence increases the gravity of the prognosis. Epithelioma beginning as a flat infiltration may resemble a tuberculous or syphilitic lesion, but usually other signs of these diseases are present to aid the diagnosis; in the latter the Wassermann reaction and, still more, the effect of vigorous anti-syphilitic treatment will clear up the doubt. There is a form of senile tuberculosis in which infiltration of one vocal cord may closely imitate epithelioma, more especially as the pulmonary signs are merely those of bronchitis and tubercle bacilli are very scanty in the sputum. Sometimes a piece may be removed for examination, but frequently the growth is too sessile to permit it; the piece removed must not be very small, and a negative finding is of little value, for the tip of a malignant growth cannot always be distinguished microscopically from a papilloma. Biopsy is more important since the adoption of Broders' histological method of estimating the malignancy and radio-sensitivity of tumours, but it should not be performed in cases too advanced for treatment, for it stimulates the growth and does harm.

Extrinsic epithelioma is most likely to be mistaken for tertiary syphilitic ulceration. A gumma grows and ulcerates more quickly, its edge is smoother and sharper, and its base often covered by a yellow slough. Pain has little diagnostic value, for a gumma of the upper aperture may cause severe dysphagia. Palpation with the finger is of great service, for the firm hard feel of an epithelioma is very characteristic.

Treatment.—Malignant disease cannot be removed with certainty by

the natural passages. Thyrotomy, or laryngo-fissure, is the operation of choice for removal of intrinsic cancer; it consists essentially in wide excision of the disease from the interior of the larynx after splitting the thyroid cartilage in the middle line. The results in suitable cases are probably better than those of removal of malignant disease in any other part of the body; there is now practically no immediate mortality in skilled hands, statistics show from 70 to 80 per cent. of permanent cures, and a useful husky voice remains. When, however, the growth has spread at all extensively to the arytenoid or to the subglottic region, laryngo-fissure is no longer possible and a very different picture is presented. By modern methods of laryngectomy the trachea is fixed in the lower part of the neck, aspiration of septic matter is avoided, and the mortality has been much reduced, while the results as regards freedom from recurrence have been greatly improved. The operation leaves the patient in a condition very different from that after thyrotomy; as he breathes through the tracheal opening in the neck he cannot cough or strain and has no natural voice. Nevertheless he can often produce a fairly audible whisper by means of the air in the pharynx, or with the aid of a tube leading from the tracheotomy wound into the mouth or nose, and a number of patients succeed in passing a surprisingly happy and useful existence. Subhyoid pharyngotomy and lateral pharyngotomy are operations designed to obtain access to cancers at the upper aperture of the larynx; the latter operation gives very good results in strictly limited tumours of this region. The technique of therapy by means of X-rays and radium has now been put on a reliable basis by determination of the appropriate dosage and by adequate screening; in many cases of malignant tumours of the larynx, great improvement can be obtained by both these agencies, and a considerable proportion of cures has been effected. A valuable method, in intrinsic cancer, is the insertion of radium tubes through a window cut in the thyroid ala. Great care and judgment are required in the selection of cases for these various operations, and very many come under observation too late. In these much can be done by palliative treatment; careful attention to the hygiene of the mouth and teeth is of great importance, together with mild antiseptic laryngeal sprays containing hydrogen peroxide, listerine, sanitas or phenol. For dysphagia, insufflations of powdered orthocaine, with or without benzocaine, is the most reliable remedy; cocaine is disappointing, for its effect is very transient and the resulting numbness interferes with swallowing; the judicious administration of morphine or heroin is eventually necessary, but the local application of these drugs is useless. Palliative tracheotomy or gastrotomy may be called for, and curettage or partial removal by knife or diathermy gives relief in some cases of cancer at the upper aperture.

PARALYSIS

Paralysis of a vocal cord is a frequent symptom of various diseases of the thorax and of the nervous system, and the laryngoscope is therefore of great value to the physician as an aid to diagnosis; this is more especially the case in that the common early form, abductor paralysis, causes no symptoms, and can only be recognised by laryngoscopic examination.

The original function of the laryngeal muscles is that of a sphincter to

prevent the entrance of fluid into the lungs, and this sphincter, or adductor, is the only muscle present in the larynx of the most primitive air-breathing animals; the abductors are a later addition, to assist the entry of air. Accordingly, in lesions of the nerve path, the abductor muscles are affected first and the primitive adductors are more resistant. But the function of phonation, much more recently acquired, is associated with adduction, and is under direct control of the will. Functional disturbances, therefore, always cause adductor paralysis, while organic lesions first affect the movement of abduction.

Organic Paralysis

The crico-thyroid muscle is supplied by the superior laryngeal nerve, and, when this is injured, the affected cord remains slack on phonation, but, owing to the short course of the nerve, isolated paralysis of this muscle is extremely rare; it results from surgical or suicidal wounds, or by pressure from glands, but most often occurs after diphtheria. In lesions of the vagus above the origin of this branch the signs of this paralysis are obscured by that of the other muscles of the cord. The recurrent laryngeal nerves supply all the other muscles. In any progressive lesion of the nerve-path the muscles become paralysed in a definite order, the enunciation of which is known as Semon's law; the abductors are first affected, then the tensors or thyro-arytenoidei, and finally the adductors.

In *abductor paralysis* the affected cord lies in the middle line; during phonation the sound cord adducts to meet it and the larynx appears normal, but on inspiration it is drawn outwards and backwards and appears longer than its paralysed fellow, which remains unmoved. As would be expected from the course of the recurrent nerves, the left cord is far more often affected than the right. The voice is unaltered, but, although the glottic aperture is reduced by half, there is usually dyspnœa only on exertion, except in children, in whom the narrowing of the naturally small glottis may produce sufficient obstruction to necessitate a tracheotomy.

When the thyro-arytenoid fails, the edge of the cord is concave on phonation, the cord appears narrower than its fellow, and the voice gradually becomes husky. Finally, when *total recurrent paralysis* has occurred, the cord assumes the "cadaveric position" between the middle line and the normal position of rest. On phonation, the healthy arytenoid crosses the middle line and pushes the paralysed cartilage aside; sometimes the latter drops forward and exposes its broad posterior surface, which may be mistaken for a swelling. As the cords are still able to approximate, the voice is not necessarily lost, but is hoarse and easily tired, with a characteristic breathy quality from waste of air, or a diphonic character, due to unequal vibration of the two cords.

In cases of *bilateral abductor paralysis* the cords lie together near the middle line. The voice is good, but the inability to take a full breath gives the speech a peculiar character; dyspnœa is a marked symptom accompanied by inspiratory stridor and severe paroxysmal exacerbations. When the disease progresses to complete *bilateral recurrent paralysis*, both cords remain in the cadaveric position, the dyspnœa becomes less severe but the voice is reduced to a whisper.

Diagnosis. — The diagnosis is almost entirely a matter of accurate

inspection. Obliquity of the laryngoscopic image, due to faulty position of the mirror, may cause confusion. In nervous subjects the cords are sometimes adducted on inspiration, but they will abduct naturally during the involuntary inspiration which follows a prolonged phonation. The only condition which really imitates paralysis is the fixation of the arytenoid cartilage which results from disease in or around the joint; its complete immobility with the presence of swelling or scarring often aids the diagnosis, but in old-standing cases of paralysis secondary fixation frequently occurs.

Ætiology.—The ætiology is of importance, for it is on our knowledge of their causation that the diagnostic value of these lesions depends. The movements of the cords are represented bilaterally in the cortex cerebri, and stimulation of either centre produces movement (adduction) of both cords, from which it follows that no unilateral lesion above the bulbar nuclei can paralyse the larynx, and clinically we find that it is never affected in cases of hemiplegia. The bulbar centres lie in the floor of the fourth ventricle, and here a lesion of one centre causes paralysis of the cord on the same side which, in a gradually progressive lesion, affects first the abductor muscle. Thence the nerve fibres pass in the roots of the bulbar-accessory to the vagus and recurrent laryngeal nerve; the cause of the paralysis may, therefore, be situated (1) in the medulla, (2) at the base of the skull, (3) in the vagus, or (4) in the recurrent laryngeal nerve.

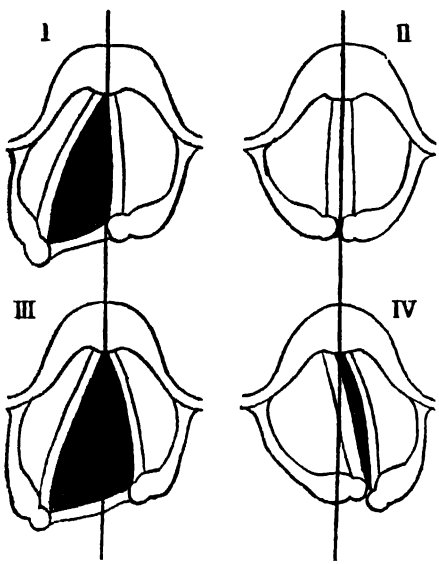

FIG. 97.—Organic Paralysis: I. Abductor paralysis of left cord on inspiration; II. Abductor paralysis of left cord on phonation; III. Total paralysis of left cord on inspiration; IV. Total paralysis of left cord on phonation. (*Lancet.*)

Paralyses of bulbar origin are often, but by no means always, bilateral. In lesions here and at the base of the skull neighbouring nerves are liable to be involved; thus, paralysis of a cord and of the same side of the palate may coexist (syndrome of Avellis), or paralysis of cord, palate, trapezius and sternomastoid from involvement of the spinal accessory roots, or persistent frequency of the pulse due to damage of the cardio-inhibitory centre or nerves. Tabes dorsalis is the most frequent cause of paralysis of central origin; it may affect one or both cords and may be associated with anæsthesia, paræsthesia or the spasmodic attacks called "laryngeal crises." In general paralysis of the insane laryngeal palsy is not uncommon. It is the rule in bulbar paralysis, and is usually bilateral, but appears late in the disease.

Syphilitic nuclear disease, pachymeningitis and gummata at the base of the brain are frequent causes, and here the ocular muscles, especially the external rectus, are often attacked.

Peripheral causes usually act by compression of the recurrent nerve, the most frequent being aneurysm, enlarged glands, tuberculous or malignant, and cancer of the œsophagus. Other causes are thyroid tumours, usually but not necessarily malignant, mediastinal tumours, cancer of the lung, pleurisy, and pulmonary tuberculosis in which the nerve, usually the right, may be involved in a lesion at the apex of the lung or by tuberculous bronchial or tracheal glands. Neuritis is a cause of laryngeal paralysis; it may be produced by the toxins of the infectious fevers, usually diphtheria, or by organic poisons, especially lead, and more rarely arsenic and alcohol. Finally, the condition is sometimes the result of traumatism, more especially surgical operations on the thyroid gland and œsophagus.

Prognosis.—Paralysis of one cord is not in itself dangerous to life; but when the cause is undiscovered the prognosis must be guarded, for this paralysis may be for a long time the only sign of serious disease; on the other hand, the recurrent nerve may be involved in some non-progressive lesion, such as a fibrotic bronchial gland, and such cases have been under observation for 20 or 30 years without change.

Treatment.—This depends on the cause. In most cases it is but a symptom of disease elsewhere and does not call for special treatment. In traumatic cases, however, the nerve may sometimes be found and sutured; afterwards, and in cases due to neuritis, strychnine and the local application of the faradic current by means of an intra-laryngeal electrode are indicated. Tracheotomy is advisable in bilateral abductor paralysis, but a plug may usually be worn in the tube, to be removed at night and whenever dyspnœa threatens.

Functional Paralysis (Functional Aphonia)

Ætiology.—Functional aphonia is a common manifestation of hysteria, and has been a very frequent symptom of war-neurosis or "shell-shock," but it should be clearly stated that the majority of cases are not purely hysterical. Anything which increases the effort of phonation, such as debility or laryngeal catarrh, predisposes to this affection, which is characteristic rather of feeble neuro-muscular tone than of hysteria; this explains how some women lose the voice completely with every slight cold, while other patients can produce a loud if hoarse voice with severe laryngeal disease.

Symptoms.—Paralysis of the adductors presents a totally different clinical picture from the organic paralysis. It is always bilateral; the larynx appears normal while at rest, but, on attempts at phonation, it is seen that the cords do not adduct into the position necessary for the production of the voice. Very commonly the thyro-arytenoidei are the only muscles which fail to act; the cartilaginous glottis is then properly closed, but an elliptical chink is left between the cords. If the crico-arytenoidei laterales are paretic, the entire glottis remains open to a variable extent, and, very rarely, the arytenoideus is affected alone, when a triangular aperture is left behind the vocal processes. The paralysis is

hardly ever complete; indeed a considerable amount of movement is usually seen, though insufficient to produce phonation. In purely hysterical cases the onset and recovery are sudden, the cough is usually not aphonic and the voice when regained is not hoarse. In some hysterical patients there is also inability to whisper.

Treatment.—In patients suffering from debility the cause should be found and treated; chronic phthisis is such a common cause of functional aphonia that it should always be thought of in this connection. There is frequently a slight degree of laryngitis and in some of these cases the failure of adduction is "myopathic," or due to inflammation of the muscles; in these the local condition must receive appropriate treatment. When the larynx is normal the voice can nearly always be temporarily restored by any powerful local stimulation, such as the intralaryngeal application of chloride of zinc, or any similar drug, or of the faradic current; but the aphonia usually recurs again, and succeeding applications are less effective, so that the most difficult cases to cure are those who have had much local treatment. Far better results are obtained by moral suasion, explaining to the patient that there is no serious disease, but that he is not using his muscles correctly, and that he can produce a good voice quite easily when the laryngeal mirror or tongue-depressor is in position. With a little elementary instruction in voice-production this is usually successful, the patient's confidence is restored and the voice does not again fail; in obstinate cases some perseverance in lessons on production is required. These methods have been extraordinarily successful with shell-shocked soldiers, but it must be confessed that such certain and rapid results are not always obtainable in nervous women.

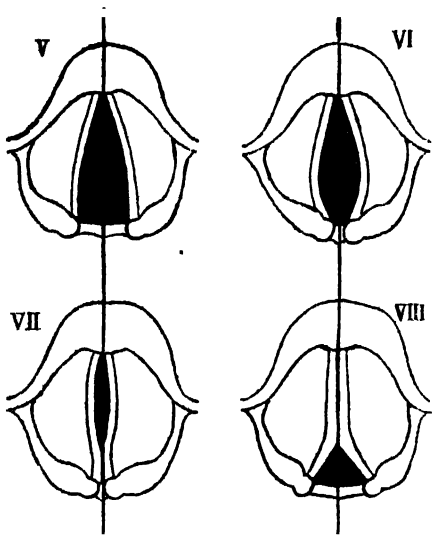

FIG. 98.—Functional Paralysis; all during attempted phonation; V. Paresis of all the adductors; VI. Arytenoideus still active; VII. Paresis of internal tensors; VIII. Paresis of arytenoideus. (*Lancet.*)

SPASMODIC AFFECTIONS

SPASM OF THE GLOTTIS

Spasm of the laryngeal muscles produces adduction of the cords, for, though the abductors are probably affected, they are overpowered by the stronger adductor muscles.

Ætiology.—(1) In the majority of cases the spasm is a reflex set up by local irritation: foreign bodies, including the laryngoscopic mirror, irritating gases; inflammation, ulceration or tumours in or near the larynx, children being much more liable than adults to spasm from local irritation. (2) Spasm is also caused by irritation of the recurrent laryngeal nerves by enlarged glands, mediastinal tumours and, especially, by aneurysm. (3) Central nervous lesions, especially tabes. (4) Functional disturbances, frequently hysterical, often associated with globus hystericus, and sometimes excited by sexual disturbances.

Symptoms.—The attacks vary much in different subjects in severity and duration. The patient is usually aware of its onset, and clutches some support or rushes to the window. The respirations are rapid and shallow, with loud inspiratory stridor, and, in the height of a severe attack, are completely arrested with all the signs of asphyxia. The subjective sensations include a horrible feeling of anxiety, but consciousness is not lost. Many cases are less acute but persist longer, even for several hours.

Prognosis.—The attacks are practically never fatal, unless a foreign body or tumour be present.

Treatment.—During the attack amyl nitrite or chloroform may be inhaled, and ampoules of these drugs should be kept on hand. Between the attacks sources of irritation should be sought for and removed, the upper air-passages brought to a healthy condition, and the general health and mode of life should receive attention. Administration of bromides may be required when the attacks recur frequently.

Laryngismus Stridulus

Ætiology.—This is a condition, clinically similar to glottic spasm, occurring in children. It is far commoner than the spasm of adults, and it has been suggested that the asphyxial attacks of laryngismus are caused by collapse of the soft and yielding cartilaginous framework of the larynx, and not solely by spasm of the muscles. It is commonest between the ages of 6 months and 2 years, but may persist later; it occurs in ill-nourished, unhealthy children, usually in association with rickets, and practically always in association with adenoids.

Symptoms.—The onset is sudden and usually at night. The child wakes gasping for breath, and a series of short noisy inspirations is followed by complete cessation of breathing and terminated by a long, crowing inspiration. There are retraction of the lower ribs and epigastrium, cyanosis and great terror and distress and, in severe cases, carpo-pedal contractions, convulsions and evacuation of urine and fæces. When the attack is over the child is perfectly normal and there is no hoarseness. Slighter and less typical attacks often occur.

Diagnosis.—This is easy if the symptoms are carefully noted; the sudden attack of dyspnœa, with complete absence of symptoms in the intervals, is quite distinctive.

Prognosis.—The prognosis is somewhat grave in severe cases; an infant rarely dies in an attack, but is often worn out and succumbs to collapse of the lungs.

Treatment.—During the attacks the face and chest may be freely

sponged with cold water, and the inhalation of amyl nitrite from a capsule broken in a handkerchief may be tried. The quickest relief can usually be obtained by drawing the tongue forward with a finger passed into the mouth to its base, a manœuvre easily performed by the mother or nurse. The attacks are so short and sharp that there is no time for the hot bath or administration of bromides frequently recommended.

Prevention involves general tonic treatment, fresh air, wholesome food and correction of digestive disturbances. The removal of adenoids is of great importance, even if not large enough to be definitely obstructive, as is the treatment of naso-pharyngeal catarrh with the usual saline lotion which, in small children, may be dropped into the nostrils from a pipette. Bromides are to be avoided if possible as depressing, but 10 to 30 drops of liquid extract of grindelia may be given 3 or 4 times a day in milk or sweetened water as recommended by Eustace Smith.

CICATRICIAL STENOSIS

Ætiology.—Suicidal and other wounds, gunshot injuries and scalds may produce cicatricial narrowing of the lumen of the glottis. After thyrotomy a web may form across the anterior commissure. In the haste of an emergency tracheotomy, the wound has often been made too high and the cricoid cartilage cut through; in these cases it generally happens that, after the subsidence of the acute condition, dyspnœa follows every attempt to remove the tube, and a stenosis is found to have resulted from swelling and narrowing in the subglottic region. Similarly, a proportion of cases intubated for diphtheria are unable to breathe without the tube, by reason of a subglottic stenosis. Lupus and tuberculosis of the larynx can produce cicatricial stenosis, and especially when the cautery has been extensively employed in treatment. Syphilis is the most fruitful cause of this condition, and the great difficulty of obtaining a cure at this stage is a powerful reason for early and thorough treatment of syphilis of the larynx. Leprosy and scleroma cause stenosis, but are rarely seen in this country. The perichondritis which is an occasional complication of enteric fever, small-pox and diphtheria commonly ends in severe stenosis.

Symptoms and Diagnosis.—The principal symptom is naturally dyspnœa, but in chronic cases it is remarkable how great may be the narrowing before dyspnœa becomes severe. The obstruction and the stridor are most marked on inspiration, in contra-distinction to tracheal stenosis where the stridor is both inspiratory and expiratory. The larynx moves downwards with each inspiration; this "respiratory excursion" of the larynx is a further diagnostic sign of laryngeal obstruction, but is not always present. The patient sits upright, with the head thrown back; whereas in tracheal obstruction he bends the neck forward to relax the trachea.

Treatment.—In all cases with decided dyspnœa tracheotomy should be first performed, and in syphilitic cases it is important that all active disease should be arrested by thorough treatment before any attempt at dilatation be begun, and the stenosis itself will often be greatly improved by such treatment. The administration of iodides is dangerous in these cases, for the increased secretion is pent up behind the stenosis and may overwhelm

the lungs. Difficulty in dispensing with the tube after tracheotomy is sometimes due to nervousness on the part of the child, and can then be surmounted by using a fenestrated tube which is plugged occasionally and by encouraging the patient to breathe through the mouth by blowing soap-bubbles or sounding a whistle. When the tracheotomy wound is too high, a low tracheotomy should be performed and the original wound allowed to close; this is often sufficient to overcome the difficulty.

The successful treatment of severe cicatricial stenosis demands the greatest skill and perseverance on the part of the surgeon as well as the patient co-operation of the sufferer. The whole circumstances of the case should be carefully considered before advising difficult and prolonged treatment. Adult patients can live active lives with a permanent tracheotomy opening, which is not so serious a disability as it is generally considered to be. If the stenosis be not too extreme, a fenestrated tube may be worn which can be kept plugged during the day, so that the patient may have the use of speech and respiration by the natural passages. In children and young people a permanent tracheotomy is more harmful, but the prospect of cure by dilatation is better; the best method of dilatation is by the use of intubation tubes.

HAROLD S. BARWELL.

DISEASES OF THE TRACHEA

INFLAMMATION OR TRACHEITIS

ACUTE TRACHEITIS

Acute tracheitis may occur from any condition leading to irritation of the mucous membrane of the trachea. When it occurs as a result of bacterial or chemical agency, the whole of the upper air-passages are usually involved in greater or less degree, and the clinical manifestations are not confined to the trachea. In some cases, however, the stress of the resultant reaction falls upon this tube, and the condition therefore requires separate consideration.

Ætiology.—1. *Microbic invasion.*—This is the commonest cause. The bacteria usually found associated with tracheitis are the so-called catarrhal organisms, such as the *Micrococcus catarrhalis*, the pneumococcus, the Freid länder pneumo-bacillus and Pfeiffer's *H. influenzæ*. It is probable that the primary organism in many cases is of filter-passing type. Frequently a member of the streptococcus group may be found, either alone or in association with one or more of those just mentioned. As with catarrhal inflammation of other parts of the upper air-passages, damp, cold or foggy climatic conditions predispose to tracheitis. It is more common in young and middle-aged adults than in infancy or in old age. Mouth-breathers are more liable to this condition. Exposure to sudden changes of temperature may be a factor in its onset.

Tracheitis may also occur as part of the clinical picture in some of the acute specific diseases, such as enteric fever, diphtheria, whooping-cough

and measles. It is often a troublesome and distressing association or sequel of true influenza.

2. *Chemical agencies.*—Irritating or poisonous fumes and vapours may lead to a very acute form of tracheitis. It may, therefore, occur in certain occupations, unless adequate precautions are taken. The use of "poison gases" in warfare has drawn widespread attention to this form of the condition, since tracheitis was an almost constant result of certain forms of "gassing." The chief chemical irritants used in the War of 1914–1918 were chlorine, phosgene and yperite, or dichlordiethyl sulphide, commonly known as yellow cross or mustard gas. Of these the last was perhaps the most irritant to the trachea, and fatal cases invariably showed tracheal lesions. Direct inhalation of steam may also induce an acute tracheitis.

3. *Mechanical causes.*—The presence of a foreign body, or the invasion of the trachea by extension from malignant growth in adjacent structures may lead to a local or even to a general tracheitis. It is noteworthy, however, that the trachea is frequently spared in occupations involving the respiration of dusty air, which leads to deposits in the lungs and bronchial glands with resulting pneumonokonioses. Although a coal miner's lungs are black, yet his trachea may be practically normal.

Pathology.—The changes found in the trachea vary from simple catarrhal inflammation to intense destructive changes with ulceration, and in some cases croupous or membranous exudate. In the catarrhal forms, the mucous membrane shows changes similar to those in bronchitis. It is at first swollen, red and dry, the vessels running across the trachea being engorged and clearly visible. Then, owing to increased activity of the mucous glands, excessive mucoid secretion occurs and the mucous membrane becomes moist, after which resolution may take place, or the process may proceed to a muco-purulent stage, when the fluid on the membrane coheres to form yellowish or green tenacious pellets. Occasionally numerous red blood cells are extruded and the tracheal exudate becomes streaked, tinged or uniformly pinkish.

In some inflammations, such as those induced by poison gases or inhaled steam, the mucous membrane may be intensely engorged and actual destruction may occur, involving even the deeper structures and the cartilages, so that greyish yellow sloughs result, which on separation leave ulcers. In diphtheria the characteristic false membrane composed of necrosing fibrin, leucocytes and bacilli may be found loosely attached to the mucous membrane, as in other localisations of this process. It may be primary or secondary to faucial or laryngeal diphtheria, either by direct extension or through diphtheritic infection of a tracheotomy wound.

In influenza the pink appearance of the trachea is of such constancy in fatal cases that it has come to be regarded as one of the most characteristic post-mortem changes found in this disease. The bright injection generally involves the lower half of the trachea, but it may occur along the whole length of this tube.

In whooping-cough the inflammatory reaction is usually less acute.

In typhoid fever small ulcers may occasionally be found in the trachea similar to those occurring more commonly in the larynx.

Symptoms.—Acute catarrhal tracheitis usually begins more or less acutely, like the common "cold," of which it is to be regarded as one form, with malaise, slight headache, and a mild degree of fever, the temperature

being usually between 99° and 100° F., rarely 101° F. The patient soon experiences a sensation of irritation behind the sternum, rapidly leading to a harsh, dry cough of noisy character. The cough aggravates the retrosternal discomfort, which develops into a sensation of rawness or soreness, making the cough very painful and distressing. If the larynx is involved at the same time, the voice becomes hoarse and sometimes lost, or reduced to a raucous whisper. In tracheitis alone the voice is usually unaffected. After from 12 to 24 hours the condition passes into the mucoid stage. The cough becomes looser and less painful, and small pellets of tenacious mucus are coughed up, usually greyish or black in town-dwellers, whitish in those in rural conditions; in either case, the mucus may be streaked with blood or even tinged a uniform pink colour; in the more acute forms it sometimes becomes yellow and more purulent. In the mucoid stage, the retrosternal soreness becomes less, the constitutional symptoms abate, while the temperature subsides and becomes subnormal. The patient often feels weak and out of health for some days, and is sometimes left with a noisy morning cough and tracheal irritation which may last for days or weeks. The aspect of the patient shows nothing characteristic. There is the general appearance of fever, malaise and discomfort. The rise of temperature and increase in pulse-rate are usually moderate. In the early stages physical examination of the chest shows no abnormality, but when exudation occurs a coarse wheeze may be audible over the trachea, particularly when the patient takes a deep breath or just before a cough occurs.

Diagnosis.—The association of catarrhal symptoms with a dry, harsh cough and retrosternal soreness, without signs of bronchitis, is almost pathognomonic. In some cases the diagnosis can be established with the laryngoscope or by endoscopy, but in most the discomfort which these examinations entail is unnecessary.

Prognosis.—This is almost invariably good, except in debilitated subjects or in those with cardiac or renal disease, in whom the process may spread to the larynx, bronchi or lungs. The usual course is from 2 days to a week, though cough and expectoration may persist for days or weeks. The condition may become chronic. To some extent the prognosis depends upon the care and treatment in the initial stage. Cases that are neglected are liable to become chronic.

Treatment.—The prophylactic and remedial treatment of acute tracheitis is practically identical with that of acute bronchitis of the larger tubes. Even in mild cases the patient should go to bed, though this may be necessary only for 1 or 2 days; but he should keep to his room till his temperature has become normal. There may be less need for expectorants than in bronchitis, and a simple saline diaphoretic mixture, with the addition later of tinct. ipecac. and tinct. opii camphorata, may be all that is necessary. Sedative inhalations, such as vapor benzoini, are useful, and counter-irritation to the sternal region is comforting and grateful to the patient. When a chronic noisy cough develops, a mixture containing small doses of apomorphine and tinct. chloroform. et morphin. co. often gives relief, or codeine linctus B.P.C.

When tracheitis occurs as part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the primary disease.

In "gassing," every effort should be made to relieve the distressing and

painful symptoms, and for this purpose morphine, either alone or in combination with atropine and strychnine, may be required. Various inhalations may be tried, and useless cough should be checked by sedative mixtures or by a linctus of heroin, morphine or codeine.

Chronic Tracheitis

Ætiology.—Chronic tracheitis may follow an acute attack, or it may develop insidiously in patients suffering from chronic laryngitis or bronchitis. Inhalation of cigarette smoke is a not infrequent cause. It is also sometimes a sequel of chronic rhinitis, especially of the atrophic form or ozæna. A certain degree of chronic tracheitis accompanies the specific lesions of syphilis and tuberculosis, which are described below.

Pathology.—Various degrees of chronic inflammatory lesions may be found. In chronic catarrhal tracheitis, the vessels are distended or engorged, and the mucous membrane of the trachea becomes thickened and more or less covered with mucoid or muco-purulent secretion, the histological changes being those of chronic catarrhal inflammation, namely, shedding of the ciliated epithelial cells, overactivity of the mucous glands, and sometimes thickening and induration of the submucous tissues from proliferative changes. A condition of perichondritis of the tracheal cartilages may, in this case, be observed, and this may result in a mammillated appearance in the internal aspect of the trachea. In ozæna, crusts similar to those in the nose and pharynx may form on the tracheal mucosa.

Symptoms.—The symptoms of chronic tracheitis are similar to those of the acute form. There is a sense of discomfort and irritation about the trachea and a chronic, almost dry cough, often worse in the morning. There is generally some scanty, sticky expectoration, mucoid or muco-purulent, darkened by carbon particles and occasionally blood-tinged.

There are practically no physical signs of this condition, except that the tracheal changes can be observed by the laryngoscope or by endoscopy of the trachea.

Diagnosis.—This is concerned chiefly with its differentiation from chronic changes in the trachea due to syphilis, tuberculosis or leprosy and to the effects of new growths. It must largely be made by endoscopic examination.

Prognosis.—The prognosis depends upon the cause. When this can be removed, as by treatment of predisposing conditions in the nose and throat, the outlook is good. When the tracheitis is due to other conditions, such as syphilis and tuberculosis, it depends upon the situation and extent of the other lesions and upon the treatment adopted.

Treatment.—This is, in its main features, similar to that of acute tracheitis, but climatic treatment may be of great importance. The patient may perhaps spend the winter months in a warm or equable and clear climate with great advantage. Vaccine treatment may also yield good results. When other conditions are concerned, such as ozæna, syphilis or tuberculosis, the treatment appropriate to them should be employed as well.

CYSTS AND TUMOURS

These are rare conditions, but require careful consideration.

Cysts

Owing to weakening of the wall of the trachea, local bulging may occur, giving rise to a cystic, air-containing swelling in the neck, in direct communication with the lumen of the trachea. Such cysts are known as "tracheoceles" or "aeroceles." They are resonant to percussion and can often be temporarily reduced by pressure.

Small retention cysts may occur in the posterior wall of the trachea, from obstruction of the ducts of the mucous glands as they pass through the trachealis muscle. They are of pathological interest only, and do not give rise to symptoms.

Simple Tumours

The most important is papilloma. It occurs chiefly in children and is usually pedunculated. When it grows in polypoid form it may lead to obstruction of the trachea low down, in which case tracheotomy may fail to give relief, and death results unless the tumour can be removed by endoscopic methods.

Other innocent tumours occur, but are rare. They include enchondrosis from localised overgrowth of cartilage, multiple enchondromata, and osteoma from ossification of a pre-existing enchondroma. Lipoma and aberrant thyroid tumours may occur, but are very rare.

Symptoms.—These tumours produce varying degrees of tracheal obstruction, and can usually only be recognised by endoscopy. Treatment is considered under that of tracheal obstruction.

Malignant Tumours

A few cases of primary carcinoma of the trachea have been recorded. Secondary growths are not common, but the trachea is often involved and infiltrated by primary carcinoma in adjacent structures, such as the œsophagus, the thyroid, the larynx, or by the extension of secondary deposits in the cervical or mediastinal glands.

Primary sarcoma of the trachea is also very rare. The growth is usually smooth and not pedunculated. Secondary deposits of sarcoma in the trachea may occur from sarcoma of distant organs, such as the kidney; or it may be invaded directly by sarcoma originating in the thymus or other mediastinal structures, and especially by lympho-sarcoma of the mediastinal glands.

Symptoms.—The tracheal symptoms and signs are usually those of obstruction, accompanied by pain. When the primary growth is in the œsophagus, antecedent dysphagia and sometimes laryngeal paralysis reveal the origin of the tracheal symptoms when they occur. In this case copious frothy mucoid expectoration is frequent, and when ulceration develops with perforation, food particles may enter the trachea, excite cough and soon lead to inhalation broncho-pneumonia or gangrene. When the growth is near the bifurcation, urgent dyspnœa is the rule, and spasmodic attacks may

occur, causing extreme distress. In most cases of tracheal growth the characteristic clanging brassy cough (gander cough) of tracheal obstruction can be heard. The trachea may be pushed to one side and its lumen distorted and obstructed by growth in the cervical glands. In mediastinal new-growth invading the trachea, the pressure signs and symptoms characteristic of that disease usually render the explanation of the tracheal symptoms apparent.

Course.—This is generally rapidly progressive.

Diagnosis.—Intratracheal growths have to be differentiated from other causes of tracheal obstruction, and the diagnosis is considered in detail under that condition. Endoscopy affords valuable confirmation if it is practicable or desirable. In œsophageal and mediastinal new-growths invading the trachea, X-ray examination may assist in diagnosis.

Prognosis.—This is hopeless, death occurring from asphyxia or from some complication or by asthenia.

Treatment.—Treatment can be palliative and symptomatic only. In obstruction, it may be possible in rare cases to give temporary relief by a low tracheotomy, but as a rule this is impossible, owing to the presence of obstruction below any point where the trachea is accessible.

THE INFECTIVE GRANULOMATA

Syphilis

The trachea may be affected in both the congenital and acquired forms.

In congenital syphilis, a progressive cicatrisation may occur, leading to stenosis. In acquired syphilis, during the secondary stage, the mucous membrane of the trachea may become generally hyperæmic, or small raised mucous patches may develop locally. In the tertiary period, gummata may occur in the trachea, the commonest site being towards the lower end. Degenerative processes, leading to necrosis and softening, eventually result in ulceration, sometimes with local sloughing of parts of the tracheal rings. In the process of cicatrisation a progressive stenosis may develop.

Symptoms.—Symptoms are those of chronic tracheitis and tracheal irritation in both the secondary and tertiary manifestations, but in the latter, signs of tracheal stenosis may develop when scarring and healing are in progress. Laryngeal involvement occurring at the same time tends to distract attention from the tracheal lesions or to obscure them.

Diagnosis.—The diagnosis of syphilis of the trachea depends upon a careful study of the history of the case, indications of tracheal irritation, laryngoscopic or endoscopic examination, the coexistence of other manifestations of syphilis, and in their absence, a positive Wassermann reaction.

Prognosis.—If the condition is recognised early, excellent results may be obtained by treatment, but it is obvious that where deep destructive changes have resulted, medicinal measures can only palliate.

Treatment.—Anti-syphilitic treatment should be administered vigorously, and after a course of neoarsphenamine, mercury or bismuth preparations should be given. Inunction seems sometimes of special value in such cases. In cases of stenosis of the trachea from cicatrisation, dilatation of the stricture by means of bougies introduced through an endoscope may be practicable and afford useful help.

Tuberculosis

Tuberculosis of the trachea is occasionally found post mortem in advanced cases of pulmonary tuberculosis, usually in those with extensive laryngeal involvement. Primary tracheal tuberculosis is unknown. The rarity even of secondary lesions in this tube is probably to be explained by the ciliated epithelium preventing lodgment of the bacilli.

Pathology.—Tuberculous lesions may occur at any part of the trachea, but they are more frequent in the lower part and on the posterior wall. When they occur they are usually numerous. There may be some general hyperæmia, or small tubercles, varying in size from a pin's head to a split pea, may be visible. Later, superficial ulceration occurs, forming irregular punched-out ulcers. Occasionally, the process may extend deeper, and erosion of the cartilages may occur, with the formation of sinuses and even fistulous communication with the œsophagus.

Symptoms.—Since tracheal tuberculosis is usually a late manifestation of advanced disease, its clinical indications are slight and are usually obscured by the more obvious laryngeal and pulmonary symptoms and signs, though if the process extends deeply and produces sinuses and fistulous tracks, it may become apparent. The actual tracheal symptoms are those of cough and retrosternal soreness.

Diagnosis.—This condition has to be distinguished from other chronic tracheal lesions, and a diagnosis can only be made from a careful review of the history, the general evidence of tuberculous disease and by the tracheal involvement which may be visible by endoscopy.

Treatment.—This must, from the nature of things, be largely palliative, and is in effect practically identical with that of laryngeal tuberculosis, notably intratracheal insufflation with orthoform and benzocaine (anæsthesine).

Leprosy

In some cases of this disease, granulomatous lesions occur in the trachea, and these may eventually give rise to tracheal stenosis, owing to the contraction of new-formed fibrous tissue. The diagnosis can only be made from the occurrence of tracheal symptoms in a case with established lesions of leprosy in other parts.

The treatment is symptomatic.

Scleroma

Although in most cases this condition affects the nose only, scleromatous lesions may be found in the trachea as a pathological curiosity. The disease in any form is rare in England, and occurs chiefly in Poland and Austria. The nodules of granulomatous tissue in the trachea may cause partial obstruction mechanically, or, on contraction, lead to actual stenosis.

TRACHEAL OBSTRUCTION

Obstruction to the lumen of the trachea may be produced by foreign bodies, by conditions originating in the trachea, and by pressure from without.

Foreign Bodies in the Trachea

The commonest route by which foreign bodies enter the trachea is through the mouth and larynx, in the acts of breathing, laughing, yawning, sighing, or before and after coughing, when food or some foreign substance is in the mouth. A piece of bone, a stud, button, false teeth, chewing gum, peas, articles of food, nuts, grains of wheat, beads or blades of grass are among the substances which may gain entrance to the trachea in this manner. Surgical operations in the mouth and throat may lead to the inhalation of a tooth, a piece of tonsil or a mass of adenoid tissue. Material vomited from the stomach, such as food, blood clot or intestinal worms, may be inhaled into the trachea. A large blood clot in hæmoptysis may temporarily obstruct it. Foreign bodies may also gain access through the tracheal wall, such as small projectiles in wounds of the neck, a piece of new growth, or tuberculous glands by ulceration through the wall.

Unless it becomes impacted, or is too large to enter one of the two main bronchi, a foreign body rarely remains long in the trachea. It either causes death with dramatic rapidity, is coughed out again, or passes down into one or other of the large bronchi or their secondary divisions, where it produces results which are described in the section on diseases of the bronchi.

Symptoms.—These depend upon the mode of entry, the size of the foreign body, and the degree of obstruction to the air current which it induces, but in general the tracheal symptoms are less urgent than those of laryngeal obstruction, and less serious than those of obstruction of one or other main bronchus. There may be intense dyspnœa, with great discomfort and alarm during the actual passage through the larynx of a small foreign body, especially if it is temporarily arrested there; but when it enters the trachea there is an almost instantaneous cessation of the acute distress, though some degree of dyspnœa may persist. The type of dyspnœa is inspiratory in the main, though a minor degree of expiratory difficulty may be apparent if the foreign body is of considerable size. There may be a definite stridor with both phases of respiration, but it is more pronounced in inspiration. If the foreign body remains loose in the trachea, which may occur if it is rounded and too large to engage in one of the main bronchial divisions, a sound of vibratory character may be heard on auscultation of the trachea, sometimes described as the *bruit de grelottement*. This may be produced by friction of the foreign body against the tracheal wall, or more commonly by the air passing over it during respiration. A paroxysmal cough may occur, caused by the foreign body irritating the sensitive posterior wall of the trachea, and during such an attack the foreign body may be forced up to the larynx, obstruct it, or cause reflex spasm with intense dyspnœa and cyanosis and a risk of suffocation, unless it drops back, is coughed out, or removed. When sudden rupture of caseous material into the trachea occurs, the lumen may be blocked and death take place rapidly.

Course.—A foreign body impacted in the trachea may give rise to septic inflammation of its walls, with subsequent cicatrisation after removal, or it may lead to secondary infective processes in the lungs, such as purulent bronchitis and broncho-pneumonia.

Diagnosis.—The history of disappearance of some object from the mouth during coughing, breathing or laughing should give rise to suspicion of an

inhaled foreign body, and this may be confirmed by seeing the object directly by endoscopy, or indirectly by means of the X-rays.

Prognosis.—This depends in the main on the nature of the foreign body, and the time elapsing before its removal. An irregular, rough or soft foreign body is more likely to induce septic complications than a smooth, hard substance. Apart from rapidly fatal results, the prognosis is better with intratracheal foreign bodies than with those reaching the bronchi. If removal is effected within 24 to 36 hours, recovery is usually rapid and complete.

Treatment.—Treatment consists in rapid removal with as little damage to the trachea and larynx as possible. This may be effected by means of forceps passed through a bronchoscope, or rarely by tracheotomy alone, when the foreign body may be coughed out through the opening or be easily removed by forceps. Inversion of the patient in the hope that gravity may assist the expiratory efforts of cough is dangerous and should only be attempted after tracheotomy has been performed. Where rupture of a caseous gland or softening new-growth occurs into the trachea, an immediate tracheotomy may be necessary.

Obstruction from Cicatrisation of the Tracheal Walls

Ætiology.—This may result from any condition leading to ulceration of the tracheal walls, with subsequent healing, such as a syphilitic gumma, or less commonly other granulomata, such as tubercle, leprosy or scleroma. Another cause is cicatrisation from wounds of the trachea, accidental, suicidal or after tracheotomy, when the incision has been made too near the cricoid, or when the wound has become infected or the tube left in too long. Scarring from damage to the trachea by the inhalation of boiling or caustic liquids or even by inhaled gases may lead to stenosis.

Pathology.—The deformity of the trachea and the obstruction of its lumen depend upon the situation and the extent of the cicatricial contraction of its walls. It may be local, producing an hour-glass constriction, or involve a long extent of the tube. Occasionally, especially in syphilitic lesions, stenosis may occur at two different levels.

Symptoms.—These depend upon the degree of stenosis, the rapidity with which it develops, and the condition of the larynx, bronchi and lungs. When the stenosis is produced gradually, as in cicatrisation, a degree of obstruction may result, greater than would be compatible with life if suddenly induced. In the early stages of a progressive stenosis, slight dyspnœa may be present on exertion, and during sleep a faint stridor may be audible, disappearing when the patient is awake. As the contraction progresses, the dyspnœa becomes more marked, and a definite and persistent stridor develops, at first inspiratory only, though expiration may become both noisy and obstructed. The patient may experience a sensation of obstruction referred to the neck or under the sternum, accompanied by pain and irritation, leading to cough, which may be dry, noisy and metallic, or accompanied by more or less frothy sputum, if the primary condition is associated with widespread tracheitis. The voice may lose tone and volume, and the patient talk more quietly than normal and with some evident effort. In advancing stenosis, sudden and alarming attacks of dyspnœa may occur,

leading to cyanosis and threatening suffocation. These attacks are usually due to an accumulation of mucus at the site of the stenosis. The patient in advancing degrees of obstruction cannot lie down, and generally sits leaning forward with chin depressed. It may be noted that the extraordinary muscles of respiration contract forcibly, and yet the laryngeal excursions may be small or hardly noticeable, in contrast with those of laryngeal obstruction in which they are maximal. This distinguishing sign was first pointed out by Gerhardt, and is of value, but unfortunately it is not absolute and cannot, therefore, be regarded as pathognomonic. On auscultation over the trachea, a noisy roar may be audible, of maximum intensity near to the obstruction, whereas the breath-sounds over both lungs may be deficient, although the stridor may be conducted bilaterally.

Course.—The course of cicatricial stenosis is usually progressive, unless arrested by treatment, and the dyspnœic attacks become more frequent and alarming.

Diagnosis.—Tracheal obstruction from cicatrisation has to be distinguished from laryngeal obstruction, in which the symptoms are usually more acute and more urgent. Gerhardt's sign described above may also be suggestive. It has also to be differentiated from obstruction due to pressure from without (*vide infra*). The only reliable method of distinction is by direct inspection with the bronchoscope.

Prognosis.—Early syphilitic stenosis may be arrested by appropriate anti-syphilitic treatment. Obstruction due to other granulomatous conditions varies with the severity and extent of the primary lesions. Caseous material or degenerated growth ulcerating into the trachea is usually immediately fatal, or leads to death within a few days from pulmonary complications.

Treatment.—Rest, avoidance of exertion, smoking and alcohol should be advised. The patient's fears should be allayed and symptomatic treatment ordered, such as sedative inhalations or a linctus to check useless cough. In syphilitic stenosis vigorous anti-syphilitic treatment with neoarsphenamine,[1] mercury or bismuth preparations should be given. A low tracheotomy may be necessary for an intractable stricture high up in the trachea. In some cases where an ordinary tracheotomy cannot be performed below the stricture, it may be possible to insert Koenig's long tracheotomy tube through an opening in the trachea made above it. In other cases, dilatation of a fibrous stricture by bougies passed through an endoscope may be feasible.

Obstruction from External Pressure

Pressure on the trachea may occur in the neck or in the mediastinum.

Causes of pressure in the neck.—Strangulation, throttling or garotting leads to death by occlusion of the trachea and suffocation. Enlargement of both lobes of the thyroid body may cause lateral compression of the trachea, until eventually its lumen is reduced to a narrow slit—the so-called "scabbard trachea." Irregular or unilateral enlargements on the other hand cause deviation of the trachea, with kinking of its lumen. Other less common

[1] According to Mr. Harold Barwell, administration of potassium iodide is very dangerous, as it increases the secretion which is pent up behind the stenosis. It may be given in combination with belladonna, but it is better withheld until the severity of the condition has been relieved by neoarsphenamine.

causes of compression of the trachea are enlargement of the cervical glands from tuberculosis, malignant disease, Hodgkin's disease or leukæmia. The trachea may be pressed on from behind by a foreign body impacted in the œsophagus, or by a bony tumour arising from the vertebræ.

Causes of pressure in the mediastinum.—An aneurysm of the aortic arch may press directly upon the trachea at, or near, the bifurcation and cause obstruction. Similarly deep pressure may be caused by a retrosternal goitre, a persistent and enlarged thymus, or a thymic abscess, mediastinal glands enlarged from any cause, usually malignant disease, a dermoid cyst or a bony tumour originating in the sternum.

Symptoms.—The symptoms are in the main identical with those of stenosis of the trachea from intrinsic causes, with the special symptoms due to the primary external condition superadded.

Diagnosis.—This may be simple and obvious, as in those cases due to pressure from tumours in the neck, whereas, in those due to mediastinal pressure, it is usually only possible after a careful survey of all the symptoms, and is in brief identical with that of aneurysm or mediastinal new-growth, to which reference should be made. In some cases X-ray examination may give valuable information.

Prognosis.—This is good in obstruction due to causes in the neck other than malignant disease, but it is almost uniformly bad, indeed hopeless, in obstruction due to mediastinal causes, with the exception of abscess and some thymic conditions.

Treatment.—The treatment is that of the primary condition. In goitre and tuberculous glands, in simple tumours, cysts and some thymic conditions, operation may be possible and may effect complete cure. In those due to mediastinal pressure, especially from aneurysm or new-growth, treatment, in most cases, can be only palliative or symptomatic, and directed to the relief of pain, dyspnœa, cough and distress.

INJURY

Direct violence to the trachea has been known to cause rupture when the chin is raised upwards and the trachea is, therefore, extended.

R. A. Young.
G. E. Beaumont.

DISEASES OF THE BRONCHI

BRONCHITIS

Inflammation of the bronchi, or bronchitis, is one of the commonest maladies and may be induced by a variety of causes. These, in the main, fall into three groups: bacterial, chemical and mechanical, similar to the causes of tracheitis, which is, indeed, in many cases, a concomitant or antecedent of bronchitis, so that tracheo-bronchitis would be a more accurate designation of the majority of cases. At the same time it should be recognised

that the trachea may be alone or predominantly affected, while, on the other hand, in many cases of bronchitis of the smaller tubes, the trachea may escape, or be only slightly involved.

Bronchitis is so varied in its extent and in the form and severity of its manifestations that a satisfactory classification is somewhat difficult to formulate. We propose to consider the clinical manifestations of bronchitis according to the following classification:

1. ACUTE FORMS—(*a*) Catarrhal bronchitis, (1) of the larger tubes, (2) of the smaller tubes; (*b*) suppurative; (*c*) secondary bronchitis; (*d*) bronchitis due to mechanical and chemical agencies; (*e*) fibrinous.

2. CHRONIC FORMS—(*a*) Catarrhal, (*b*) suppurative, (*c*) secondary, (*d*) due to mechanical agencies, and (*e*) fibrinous.

1. ACUTE BRONCHITIS

ACUTE CATARRHAL BRONCHITIS OF THE LARGER TUBES

Synonyms.—This condition is often called Bronchial Catarrh, or Acute Tracheo-bronchitis.

Ætiology.—*Predisposing causes.*—Climate and latitude undoubtedly play an important part. Catarrhal bronchitis is rare in polar and arctic regions and near the equator, but is very prevalent in damp and foggy climates. In England, attacks are common in late autumn, winter and early spring. It is probable that some degree of hereditary predisposition occurs, since "weakness of the chest" is common in some families. Owing chiefly to greater exposure, the disease occurs more frequently in men than in women. It is most common at the extremes of life, infancy and old age, but it is not infrequent at any age. Fatigue and privation play their part, and exposure to cold, wet or fog so frequently seems to initiate the attack that it is often regarded as the exciting cause. Scoliosis, kypho-scoliosis and other malformations or deformities of the chest predispose to bronchitis, and some of them are induced or aggravated by bronchitis early in life. Chronic cardiac and renal disease both render their subjects more liable to bronchitis, as do also conditions of the nose and pharynx which lead to mouth-breathing, in consequence of the inhalation of air which is unwarmed and unfiltered by the nose. In childhood, dentition seems to be a frequent predisposing condition.

The exciting cause is usually one of the catarrh-producing organisms, and one or more of the following may be found in the sputum: the pneumococcus, Friedländer's pneumo-bacillus, streptococci, *Micrococcus catarrhalis*, staphylococci, *M. tetragenus*, and filter-passing organisms. It may also be caused by the *Spirochæta bronchialis*.

Pathology.—The changes induced in the bronchi are similar to those in the nasal mucosa in coryza and in the trachea in tracheitis. Three stages may be described: An initial dry stage, when there is active hyperæmia of the bronchial mucosa, with exudation into the submucous layer, causing temporary diminution of the bronchial secretion from occlusion of the mucous ducts. The second or mucoid stage is associated with copious discharge of mucoid secretion, owing to increased activity of the mucous

glands, this secretion being mixed with shed ciliated epithelial cells and scanty leucocytes. Sometimes in acute cases a few red blood corpuscles are present. The third stage is that of resolution, though not infrequently a muco-purulent stage occurs, when the sputum becomes less copious and greenish in colour from large numbers of pus cells.

In fatal cases the lung tissue may appear slightly distended and red, while the bases may be sodden from œdema. On section, the bronchi appear injected and the mucosa is swollen. On squeezing the lung, beads of mucoid fluid or muco-pus exude from the cut ends of the bronchi. There is no consolidation and the lung tissue floats in water.

Symptoms.—An attack of acute bronchitis generally begins suddenly, with malaise, aching in the limbs, and a sense of oppression in the chest. If the trachea is also involved, there is the characteristic feeling of rawness under the sternum. The temperature rises, varying from 99° to 100° F. in mild cases to 103° F. in more severe ones. The cough is at first dry, irritating and ineffective, but in a few hours it becomes looser. The sputum in the early stage is scanty, tenacious and sometimes streaked with blood; it then becomes copious, mucoid and frothy in character, and is found to contain mucus, shed epithelial cells, leucocytes and red blood corpuscles. Later it lessens in quantity and may become thick, yellow and muco-purulent. With the onset of expectoration there is generally an abatement in the symptoms, the rawness under the sternum disappears, and the feeling of pain or soreness about the pectoral muscles and the costal attachments of the diaphragm lessens. The febrile reaction may last only 3 or 4 days, but the cough and expectoration may go on for 10 days or longer, gradually diminishing, until they are present only night and morning, and then cease completely. SIGNS

In the early stage the patient is flushed and the breathing may be slightly increased in rate, but it is rarely or never laboured, unless emphysema co-exists. Vocal fremitus is unaltered, but rhonchal fremitus may sometimes be felt over one lung or both. The chief physical signs are discovered only on auscultation. The breath-sounds may be harsher and higher-pitched, particularly in infants and children, but they remain vesicular, and expiration may be prolonged. The voice conduction is unaltered. As a rule rhonchi, either sonorous or sibilant, according to the size of the bronchus in which they are produced, are audible over both lungs, and during the mucoid stage bubbling râles may be heard, especially at the bases.

Complications and Sequelæ.—Bronchitis may go on to broncho-pneumonia or may be followed by lobar pneumonia, fibroid induration or bronchiectasis. It may lead to chronic bronchitis, or be followed by active tuberculosis. Occasionally acute interstitial emphysema may result from violent coughing.

Course.—This is variable. The patient may be convalescent in from 7 to 14 days, but cough, expectoration and a condition of debility may continue for several weeks, though, in this case, the possibility of pulmonary tuberculosis should always be considered.

Diagnosis.—The diagnosis of bronchitis is usually easy, owing to the characteristic rhonchi, but it is important to differentiate primary bronchitis from bronchitis occurring as a secondary condition in acute specific fevers and other diseases.

Prognosis.—Bronchitis of the larger tubes is rarely fatal, except when it occurs in infants or the aged, or as a complication of advanced cardiac or renal disease.

Treatment.—PROPHYLACTIC.—This consists in the avoidance of stuffy, ill-ventilated rooms and places of entertainment when catarrhal infections are rife. In mouth-breathers, steps should be taken to deal with the conditions of the naso-pharynx inducing this habit, and instruction in normal breathing given. In dusty occupations, suitable measures should be taken to minimise the irritant particles in the air, as is now done in most factories and workshops. Where poisonous gases have to be encountered, some form of efficient gas-mask should be utilised.

Prophylactic inoculation by vaccines, either from stock mixtures such as are now available, or from autogenous cultures, is now being extensively used, and with some success. An autogenous vaccine is usually to be preferred, if possible. The dose given depends upon the organism and varies from 1 to 50 or 100 millions. Two or three doses at intervals of 7 to 10 to 14 days are usually given in the case of the stock vaccines, whereas with the autogenous a course of 6 to 12 gradually increasing doses is given at intervals of about a week.

CURATIVE.—No matter how mild the attack may be at the onset, the patient should be kept in bed. This may only be necessary for 1 or 2 days, but he should keep to his room till his temperature has returned to normal. The Turkish bath taken by some patients at the first onset is unwise and should be discouraged. The room temperature should be kept at 60° to 65° F. While the temperature is raised the diet should be the ordinary, simple, liquid diet suitable to febrile conditions, namely, milk, weak tea, cocoa and simple gruels, broths or one of the many invalid foods. The patient is often thirsty, and warm or hot demulcent drinks, such as toast water, fruit juices in hot water, and linseed tea sometimes afford great comfort. The air of the bedroom may be moistened by means of a steam kettle in the dry stage, but the use of a steam tent is to be avoided. Local applications over the sternum, acting as counter-irritants, seem to give some relief to the distressing soreness so often complained of. A mustard leaf or one of the medicated wools is the most easy to apply, but a linseed poultice, kaolin poultice or a liniment, such as camphorated oil or the acetic turpentine liniment, may be ordered. Some patients find a cold or hot compress to the neck comforting. Medicated inhalations may be used, either in a special inhaler or in a domestic substitute, such as a jug. At first vapor benzoini —60 minims to the pint of water at 160° F.—is the most comforting, but in later stages vapor pini (olei pini, min. 10; mag. carb. levis, gr. 10; aquam ad min. 120)—120 minims to the pint—or a dry inhalation of creosote, terebene and spirits of chloroform may be useful. It is often wise to start treatment with an aperient, unless this is contra-indicated. In the dry stage a simple saline diaphoretic mixture may be given, with tinct. ipecacuanhæ or vin. antimoniale in small doses. One-drop doses of tincture of aconite are also sometimes given. When expectoration starts it may be encouraged by saline and stimulating expectorants, such as ammonium chloride or carbonate, combined with squills and flavoured with syrup of tolu or of Virginian prune. For the first night it may be well to give 10 grains of Dover's powder to relieve discomfort and secure sleep.

During convalescence the patient should take care to avoid chill and should be given a more liberal diet. A mixture of strychnine and phosphoric acid may be given for a few days, and a linctus or lozenge containing small doses of diamorphine (heroin) or other sedative, to lessen the ineffective cough, which not infrequently occurs, especially at night. Convalescence is usually shortened by a few days' stay at the coast, especially the south.

When bronchitis occurs as a part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the particular disease.

Acute Catarrhal Bronchitis of the Smaller Tubes

Synonym.—Capillary Bronchitis.

It is open to question whether this condition exists as a separate entity. When the finer bronchi and bronchioles are inflamed the alveoli invariably become involved, since very little swelling of the bronchiolar walls is sufficient to occlude the lumen of the tube, with the inevitable production of an area of lobular collapse. The transition from this condition to actual lobular pneumonia is a very small one. In any case, the causes, the symptoms and the treatment of capillary bronchitis and broncho-pneumonia are identical. (See Secondary Broncho-pneumonia.)

Acute Suppurative Bronchitis

Synonyms.—Sometimes called Acute Purulent Bronchitis, or Suffocative Catarrh.

This condition was brought into prominence during the Great War. In 1916 and 1917 it appeared in epidemic form amongst the British troops in England and France. Although it was then regarded by some observers as a new disease, it is more probable that it was, in reality, an epidemic form of a condition usually rare and sporadic and previously termed "suffocative catarrh." That name has unfortunately been applied loosely to a number of conditions associated with acute dyspnœa.

Ætiology.—*Predisposing causes.*—The exceptionally severe winter of 1916–17, together with conditions of overcrowding in huts and billets, were undoubtedly concerned in the epidemic just mentioned. The condition affects young adults chiefly, and is much more common in men. Over-exertion, fatigue and debility predispose to it, but the disease may occur in robust and healthy persons. A history of chill may be given, but often no obvious cause can be discovered.

Exciting cause.—The organisms usually found are the pneumococcus and Pfeiffer's *H. influenzæ*, the latter being reported in 90 per cent. in some series of cases. The *Micrococcus catarrhalis* is also sometimes present.

Pathology.—A very intense inflammation occurs in the medium-sized and small bronchi, leading to an exudate rich in leucocytes. The inflammatory process may extend to the alveoli, which then contain a fibrinous fluid, with entangled red cells. The condition occurs in both lungs and is usually almost universal, no portion being spared. Post mortem the lungs are heavy and red in colour. On section the bronchi are found to contain a thick yellow purulent fluid. Small areas of collapse and sometimes of broncho-pneumonic consolidation are seen, and there is usually œdema of the

bases. Plastic pleurisy is not infrequent, and the glands at the root of the lung are enlarged.

Symptoms.—The onset is usually abrupt, often in young people apparently in robust health. A definite chill may occur, or only coryza and general malaise, with aching of the muscles. The temperature rises quickly and may reach 104° F. early in the disease. A cough soon develops and extreme dyspnœa is a characteristic feature. Expectoration starts early, often on the second or third day. At first it may be streaked with blood, but it soon becomes yellowish green and nummular; it consists of almost pure pus; there is often as much as 5 or 6 ounces in 24 hours. In most instances there is great prostration. In grave cases the patient becomes unconscious and loses control of the sphincters.

There is intense cyanosis, the face, lips and ears being purple. Respiration is rapid, 30 or 40 per minute, and the accessory muscles are often in full action. Palpation and percussion may not show any abnormality though slight dullness is sometimes present at the bases. At first no signs may be discovered on auscultation, but soon the breath-sounds become largely obscured by medium-sized bubbling râles, often audible from apex to base, both front and back. The pulse is frequent, the right heart may dilate and the heart-sounds become weak.

Complications and Sequelæ.—In severe cases recurrent bronchitis, broncho-pneumonia, fibroid disease or emphysema may follow.

Course.—In favourable cases complete restoration to health results. In severe cases the course is rapid, the patient becomes comatose from toxæmia, expectoration ceases and death occurs from exhaustion in 2 or 3 days from the onset. In other cases the disease may last for weeks and proceed to recovery or death.

Diagnosis.—The early occurrence of marked dyspnœa and cyanosis, the expectoration of copious pus, and the widespread râles without dullness are very suggestive of acute suppurative bronchitis. The disease must be differentiated from other conditions described as acute suffocative catarrh that are associated with extreme dyspnœa and cyanosis.

Acute pulmonary œdema is usually afebrile, and the sputum is albuminous, frothy and copious. The condition leading to it, such as cardiac or renal disease, may be apparent.

Capillary bronchitis or broncho-pneumonia may give rise to difficulty, but in these conditions the sputum is scanty, tenacious, sometimes rusty, and but rarely purulent; moreover, cyanosis and dyspnœa develop late and depend upon the extent of the disease and the condition of the right side of the heart.

Pneumonia of the wandering type may simulate this condition, but the character of the signs, with dullness and tubular breathing, and the rusty sputum, usually render diagnosis easy.

Prognosis.—This is very grave. The mortality is high, often as much as 50 per cent. Cases extending to 3 weeks or more with swinging temperatures usually recover.

Treatment.—Cases of this disease should be isolated. If there are indications of an epidemic spread, prophylactic inoculations with a vaccine made from the special strain of pneumococci concerned may be useful in limiting it. In any future epidemic, a trial should be made of sulphapyridine

(M. & B. 693). The steam tent and the inhalation of medicated vapours, such as vapor benzoini, may give a little relief to the dyspnœa. Oxygen should be administered either by means of an oxygen tent, the double nasal catheter or the B.L.B. mask. Venesection may give temporary relief, but produces no lasting effect. Ammonium carbonate and potassium iodide are generally recommended. Stimulants, such as brandy and strychnine, should be given freely, and hypodermic injections of nikethamide (coramine) or leptazol (cardiazol) may be given.

Secondary Bronchitis

Ætiology.—Bronchitis, usually of catarrhal type—indistinguishable as regards symptoms and signs from primary acute catarrhal bronchitis—occurs as a definite part of many acute infectious diseases and as a complication in others. Among these may be mentioned measles, whooping-cough, influenza, the enteric group, small-pox, diphtheria, malaria and plague. Acute nephritis of infective origin is often accompanied by acute bronchitis. Other conditions associated with bronchitis are pulmonary tuberculosis, glanders, secondary syphilis, pleurisy and gunshot wounds of the chest.

Diagnosis.—Bronchitis is easy to recognise, but it is important not to overlook the fact that it may not be the primary condition. In all cases of bronchitis in the early stages, the possibility of a primary acute specific infection should be borne in mind. The diagnosis is also of importance in regard to treatment—for example, in malaria, nephritis and syphilis, in which treatment directed to the primary condition may be more helpful than the ordinary treatment of catarrhal bronchitis.

Bronchitis due to Mechanical and Chemical Agencies

Ætiology.—*Mechanical.*—Attacks of acute bronchitis may be caused by the inhalation of dust-laden air. In occupations where the worker is liable to inspire fine particles of carbon, silica, steel, iron, asbestos or kaolin, acute bronchitis may result, but more often these conditions lead to chronic bronchitis and pneumokoniosis. Pressure on a bronchus by aneurysm or new-growth, or irritation by the presence of a foreign body, may induce local acute bronchitis. The symptoms and signs are practically identical with those of the catarrhal form and need no special description.

Chemical.—Acute bronchitis may follow the inhalation of chemical irritants, either as a result of occupation, accidents, attempts at suicide, or the use of poison gases in warfare. Special attention has been drawn to this subject by the large number of cases of " gassing " dealt with in the War of 1914–1918. Death not infrequently occurred, much acute suffering was caused, and some permanent damage has resulted in many cases which recovered. " Mustard gas " produces its chief effects upon the skin, the eyes and the bronchi. A fibrinous exudate forms on the mucosa as a false membrane, which separates as a slough. The suffocative gases chlorine and phosgene affect the alveoli primarily and more intensely. Chlorine inhaled in a concentration of 1 in 10,000 causes a rapid alveolar flooding with a serous and highly albuminous fluid, and if the victim does not die at once he is liable to suffer from an acute bronchitis. A condition called bronchiolitis fibrosa

obliterans may occur as a sequel. It is often associated with asthmatic dyspnœa.

Symptoms.—These are similar to those of acute catarrhal bronchitis, but there is great pain, distress and almost constant cough, often with copious expectoration.

The treatment is referred to under the heading of Tracheitis, and is, in the main, symptomatic and directed to the relief of pain, useless cough and distress. If there is cyanosis, oxygen should be given continuously if necessary by double nasal catheter or B.L.B. mask.

Acute Fibrinous Bronchitis

Synonym.—Acute Plastic Bronchitis.

Definition.—A comparatively rare acute disease in which there is inflammation of the bronchi, with the formation of casts. These may be hollow or solid, and are coughed up in the expectoration.

Ætiology.—The cause of the disease is unknown. It is more common in males, and is met with both in children and in adults. It may begin as a primary catarrhal bronchitis, or develop as a complication of enteric fever, measles or pulmonary tuberculosis. Such organisms as the pneumococcus or a streptococcus may be found in the casts.

Pathology.—The casts may involve the main bronchi only, or more frequently the smaller ones and the bronchioles. They are greyish white, solid or tubular, and when large, bear the impress upon their exterior of the bronchial walls in which they have been enclosed. Thus, when a cast extends up to the lower portion of the trachea, the indentations made by the tracheal rings may be seen impressed upon it. The fine terminations generally show a spiral moulding. Chemically, they consist of fibrin or of fibrin and mucin. Post mortem the casts may be seen in some places *in situ*; in other areas the bronchi from which they have been expelled may be recognised. The bronchial mucous membrane is at times acutely inflamed, red in colour, with the lining epithelial cells desquamating, or it may appear pale and unaffected. There is usually a certain degree of emphysema, and there may be collapse of lung tissue beyond the site of obstruction.

Symptoms.—The disease generally begins somewhat abruptly with a cough and malaise. In the course of a few days the patient becomes considerably worse, dyspnœa develops and a certain degree of pyrexia, but the temperature is often not more than 99° or 100° F. The dyspnœa becomes more intense, and is the prominent and all-important symptom. The face is seen to be cyanosed, the alæ nasi and the accessory respiratory muscles are in violent action, sometimes with retraction of the intercostal spaces. There may be diminished movement of the chest, either bilateral or unilateral. If there is unilateral pulmonary collapse the heart may be slightly displaced towards the same side. Vocal fremitus may be normal or locally diminished. The percussion note is somewhat hyper-resonant over the anterior chest-wall, but behind there may be some degree of dullness over one or other lobes. If the bronchi are unilaterally affected there may be dullness limited to one lower lobe, with diminution of air entry and no adventitious sounds. Vocal resonance over the affected area is lessened. There is usually some diffuse bronchitis, as indicated by the presence of rhonchi or râles. Marked stridor

is sometimes heard with respiration. A special sign, the "bruit de drapeau," has been described when the cast lies free in the bronchial lumen. It is a dry clicking sound, caused by the flapping of the cast against the wall of the bronchus as the air passes over it. The ordinary sputum does not show any peculiarities. It may, however, show Curschmann's spirals, Charcot-Leyden crystals and eosinophile cells, and it may be absent until the crisis occurs. This consists in the expectoration of the cast after a violent fit of coughing. The cast may be stained with blood, or there is sometimes actual hæmoptysis. The peculiar nature of the expectoration often escapes notice, unless it is examined by floating in water, when a large intact cast is revealed. The dyspnœa ceases immediately after the cast has been expelled.

Complications and Sequelæ.—Emphysema may occur as the result of the violent coughing, or the disease may become chronic, recurring at intervals of varying duration. The most serious complication is laryngeal obstruction, caused by the cast becoming impacted between the vocal cords.

Course.—The disease is generally self-limited, terminating with the separation and expectoration of the cast. The acute stage does not, as a rule, continue for more than 12 to 24 hours.

Diagnosis.—The stridor and respiratory obstruction are suggestive of œdema of the glottis, but auscultation will show that the site of the lesion is lower down the respiratory tract. Asthma, and all causes of laryngeal and tracheal obstruction, must be excluded. The dyspnœa and the presence of signs localised to one lobe may suggest an active lobar collapse, or a lobar pneumonia, but the dyspnœa is more intense than is met with in either of these conditions. Casts are expectorated in diphtheria, pneumonia, chronic disease of the heart, pulmonary tuberculosis and hæmoptysis. The casts of acute fibrinous bronchitis are firmer than those found in these affections, and are expectorated in long pieces, showing the many branches and bifurcations of the bronchial tree.

Prognosis.—The immediate outlook is fair. Death may occur in the first attack, or recurrences may take place, which lead to an increasing degree of emphysema, with its usual results. The ultimate prognosis is, therefore, not good.

Treatment.—The patient should be kept in bed and treated as a case of acute bronchitis. Inhalations of medicated vapours often afford relief. Potassium iodide is believed to expedite the separation of the cast. Intratracheal injections of olive oil or lime water have been recommended, as the casts tend to dissolve in the latter. Tracheotomy instruments should always be at hand in case of laryngeal impaction.

2. CHRONIC BRONCHITIS

Chronic bronchitis is perhaps even more difficult to classify than the acute varieties, each one of which may have its counterpart in chronic form, so that the same classification may be followed. At the same time it must be admitted that, especially in the catarrhal forms, the clinical manifestations are somewhat varied

Chronic Catarrhal Bronchitis

Ætiology.—The causes are practically identical with those of the acute form, of which it is in most cases a sequel.

This affection may commence at any age, although it is more common in middle life and with advancing years. Men are more frequently affected than women. It seems also to have a special incidence in some families. It is more common in damp and foggy climates, and is favoured by urban conditions and by dusty occupations. It starts each winter with a more or less acute catarrhal attack, but each year the summer intermission becomes shorter, until the bronchitis persists throughout the year. It tends to produce emphysema and is aggravated in turn by this condition. It is especially favoured by cardiovascular lesions, such as valvular defects and arterial disease; also by gout, chronic nephritis, syphilis and alcoholism. Conditions associated with chronic cough predispose to it, notably emphysema, asthma, arrested pulmonary tuberculosis, mouth-breathing and cigarette-

The bacteria found are practically identical with those in acute bronchitis, the commonest being the pneumococcus, Friedländer's pneumobacillus, *Micrococcus catarrhalis*, streptococci and staphylococci. Mixtures of two or more of these may be present. A rarer cause is bronchial spirochætosis, from infection with the *S. bronchialis*.

Pathology.—The bronchi show chronic inflammatory changes of a catarrhal nature. The walls are thickened from chronic hyperæmia and also from productive changes in the connective tissues. The mucous glands may be hypertrophied or atrophied, and there may be widespread desquamation of the ciliated epithelial lining of the bronchi. In long-standing cases there is usually some peribronchitis, leading to cylindrical bronchiectasis and distortion of the bronchi by fibrosis. There is almost invariably a greater or less degree of emphysema, which may be generalised or only marginal. Post mortem, the lungs are generally red and somewhat engorged, but if much emphysema has resulted they may be paler than normal. On squeezing the lung after section, pus or muco-pus exudes from the cut bronchi, and there is usually some evidence of œdema at the bases.

Symptoms.—A patient with chronic bronchitis complains of his "chest." By this he means that he suffers from cough, expectoration and shortness of breath on exertion. The cough varies greatly in its severity. During the warm weather the patient may be completely free, and yet suffer for years from a winter cough. It may occur frequently throughout the day and in attacks at night, or only in the mornings and evenings.

The expectoration varies considerably in quality and quantity, so much so that the old classifications of chronic bronchitis were based on this factor. Thus, there may be practically no sputum or only small tenacious pellets, the "crachats perlés" of Laennec; on the other hand, there may be a profuse expectoration resembling unboiled white of egg diluted with water, constituting the form described as "pituitous catarrh" or "bronchorrhœa serosa." Usually the sputum is mucous or muco-purulent and contains greyish-black particles mixed with a frothy fluid. The dyspnœa is largely due to the accompanying emphysema, and so indicates the degree of chronicity of the disease. At first the patient may only notice that he gets out of breath on going upstairs or on mounting slopes, but later even walking on the level causes dyspnœa.

Slight rises of temperature occur in the acute exacerbations of the catarrhal process. Slight cyanosis is frequently observed, especially after

exercise, when the accessory respiratory muscles are called into play. Sometimes rhonchal fremitus is felt. Movement of the chest is restricted by emphysema, and the percussion note then becomes hyper-resonant. On auscultation, expiration is prolonged and sonorous or sibilant rhonchi are heard all over the lungs, with bubbling râles if there is thin secretion in the smaller bronchi. On the other hand, rhonchi may be scanty or only occasionally heard. Voice conduction is unaffected. The fingers may be slightly clubbed, and further evidence of venous obstruction apparent in the dilated venules on the cheeks or along the costal attachments of the diaphragm.

Complications and Sequelæ.—The following changes may occur in the lungs—peribronchial fibrosis, bronchiectasis and emphysema. Asthma or attacks of bronchial spasm sometimes form a complicating factor in chronic bronchitis, especially in the cases of so-called bronchorrhœa. The increased cardiac strain may lead to right-sided dilatation, with basal pulmonary congestion, ascites and œdema of the legs. Late in the disease, as the result of the cyanosis, a peculiar form of confusional delirium is met with, which is worse at night.

Course.—The disease once firmly established, unless relieved by suitable climatic treatment, remains chronic and becomes progressively more severe as further damage is wrought in the lungs with each hibernal exacerbation. As the emphysema develops, a vicious circle is initiated, the aerating power of the lungs diminishes, and finally cardiac failure ensues.

Diagnosis.—Chronic bronchitis must be distinguished from pulmonary tuberculosis, bronchitis secondary to heart failure, and from bronchiectasis. In tuberculosis with bronchitis there is generally wasting, and often flattening 1
of the chest-wall, owing to fibrosis of the lungs. In all cases where the summer intermission of the symptoms fails suddenly rather than lessens gradually, tuberculosis should be suspected. The diagnosis is clinched by the presence of tubercle bacilli in the sputum. In bronchitis secondary to 2
heart failure, in addition to the cardiac signs, the râles in the lungs are chiefly basal and the rhonchi are not so universally distributed. In bronchiectasis 3
the signs are usually characteristic and often limited to one lobe. The X-rays may afford useful aid in diagnosis.

Prognosis.—The immediate prognosis is good, the ultimate is bad. Much depends upon the patient's social condition and opportunities for treatment, especially in respect to climate. The expectation of life of a patient suffering from chronic bronchitis is considerably shortened.

Treatment.—Those subject to chronic bronchitis should live in a warm, equable and dry climate. In England the south-western districts are best, but it is advisable to winter farther afield if possible, either on the Riviera, the north coast of Africa, or in Madeira. High altitudes should be avoided if emphysema is present or if there are cardiac complications. Exposure to wet and chill is dangerous. The question of occupation is often difficult. Much time should be spent out of doors, provided that the patient is not exposed to the inclemencies of the elements; and, further, the work undertaken must not involve severe muscular efforts, or the inhalation of dusty or irritant particles.

In England it is difficult to find an outdoor occupation conforming with these desiderata, consequently light indoor work in a good atmosphere should be advised. Clothing should be warm but light, and afford special

protection to the chest without overloading, as some patients are liable to do. Excesses in diet are to be avoided, also alcohol and heavy smoking. The general nutrition should be well maintained, and many patients, especially those of spare habit, seem to derive great benefit from cod-liver oil during the winter months.

If cough is troublesome and expectoration tenacious or scanty, various combinations of expectorant remedies are useful, such as ammonium carbonate or chloride, tinct. ipecacuanhæ, preparations of squills or senega, with tolu, liquorice or Virginian prune as flavouring agents. A simple saline mixture such as ℞. Sodii bicarb., grs. 10 ; sodii chlorid., grs. 3 ; sp. chlorof., min. 5 ; aquam anisi ad fl. oz. 1, taken with an equal quantity of hot water in the morning or at night, may help to "clear the tubes" and give the patient a spell of freedom from cough. In older patients the ether and ammonia mixture may be given, and in cases with bronchial spasm potassium iodide with anti-spasmodics, such as stramonium, lobelia, belladonna or grindelia, may be of great value. Various antiseptic drugs, such as turpentine min. 10, terebene min. 5–10, creosote min. 3 in capsules or perles, have been recommended, and the elixir thymi et diamorphin. B.P.C. min. 60. Sedative lozenges, such as compound liquorice, heroin or codeine, are often useful in checking useless cough. Intercurrent attacks of acute bronchitis must be treated on the principles described under that condition and the patient kept indoors or in bed, as may be necessary. When an advanced degree of emphysema coexists the treatment appropriate to that condition should be applied. Sometimes benefit may follow the use of the compressed air chamber. When failure of the right heart ensues, with visceral engorgement, the treatment must be modified suitably as described under emphysema. Liniments applied to the chest-wall, especially those containing camphor, turpentine or belladonna, are soothing and afford relief. Care should be taken that any tendency to constipation is checked. In some cases, especially when the predominant organism is the *Micrococcus catarrhalis* or Friedländer's pneumo-bacillus, an autogenous vaccine prepared from the sputum ameliorates the symptoms when given in small doses. This should be considered especially in cases unable to undergo suitable climatic treatment.

Chronic Suppurative Bronchitis

Synonym.—Fetid Bronchitis.

Ætiology.—This condition is not sharply defined and is not a specific and separate nosological entity, but it is a convenient group to include cases with fetid purulent sputum. In some forms of chronic bronchitis the secretion may from time to time accumulate in the bronchi and prove offensive on expectoration. In some instances this condition becomes chronic and the expectoration is fetid up to the time of death.

Pathology.—There is chronic inflammation of the bronchi, with marked peribronchial thickening. The bronchial secretion becomes purulent, and ulceration of the bronchial wall or dilatation of the lumen may occur. Post mortem, the lungs are soft, and on section some broncho-pneumonic areas, with œdema of the bases, may be seen. Pus of an offensive nature exudes from the cut ends of the bronchi.

Symptoms.—These resemble those found in chronic bronchitis, with,

in addition, the unpleasant characteristics of the sputum, in which Dittrich's plugs may be found. These are small, yellowish bodies, with an intensely offensive odour, composed of compact secretion.

Complications and Sequelæ.—Ulceration of the bronchial walls, abscess or gangrene of the lung, and areas of broncho-pneumonia may develop. As with bronchiectasis, pyæmia sometimes ensues, with the formation of secondary abscesses in the brain.

Course.—The disease is progressive, but in the early stages there may be long remissions in which the sputum is not offensive although the bronchitis persists.

Diagnosis.—The sputum is offensive in abscess and gangrene of the lung, bronchiectasis and interlobar empyema. X-ray examination of the chest is of great value in revealing these conditions, and lipiodol or neo-hydriol investigation will usually serve to distinguish between them.

Prognosis.—As the disease becomes firmly established the patient's strength is gradually undermined from the absorption of toxins, and death ensues in the course of a few years, either from exhaustion, toxæmia or pyæmia.

Treatment.—An endeavour should be made to lessen or prevent the offensive character of the sputum. For this purpose creosote or garlic may be administered, as in bronchiectasis. If sputum is copious, postural drainage by means of a Nelson bed may be useful. Creosote vapour baths are also of great value. Apart from this, the treatment is as for chronic bronchitis.

Chronic Secondary Bronchitis

Chronic bronchitis is a common association of chronic cardiac and renal disease, and possibly also of gout. Its clinical characters do not need special description. It is only necessary to emphasise, as in the acute forms, the importance of recognising that the bronchitis is not the essential condition, and that treatment must be directed especially to the primary disease.

Chronic Bronchitis from Mechanical and Chemical Agencies

This usually proceeds to interstitial changes in the lung, and these results may be studied more conveniently under the heading of the pneumokonioses.

Chronic Fibrinous Bronchitis

Acute fibrinous bronchitis has been described above. In certain cases of chronic catarrhal bronchitis a fibrinous exudate may occur from time to time, with the formation of intrabronchial casts. There is then cough and dyspnœa, which abate with the expectoration of the cast. It therefore very closely resembles acute fibrinous bronchitis, and the treatment indicated is that described above.

TUMOURS OF THE BRONCHI

Tumours arising in the bronchi may be (*a*) simple or (*b*) malignant.

(*a*) *Simple tumours.*—The following varieties occur: Adenoma, lipoma, myxoma, papilloma and chondroma. Any of these may lead to bronchial

obstruction and, in consequence, to either collapse or bronchiectasis. Adenoma is of sufficient frequency and importance to require separate description.

(*b*) *Malignant tumours.*—Primary carcinoma or sarcoma may originate in the bronchi. In carcinoma the growth is usually of the columnar type, and arises from the lining epithelium of the bronchi or from that in the mucous glands. Oat-celled tumours also occur, and occasionally squamous-celled carcinoma. In some instances secondary deposits of carcinoma may follow very closely the paths of the main bronchi. Sarcoma may originate in the connective tissue of the bronchial walls.

Although the majority of primary malignant tumours within the lung originate in the bronchi, either from the lining epithelium or from the cells of the mucous glands, their pathological effects and clinical manifestations are in the main pulmonary, and it is therefore more convenient to describe them as tumours in the lung (see pp. 1219–1222).

Adenoma of Bronchus

Ætiology.—Adenoma of the bronchus occurs about equally in the two sexes, and usually in adults below the age of 40.

Pathology.—The tumour is at first small and of polypoid form, as a rule arising in a main bronchus, but not infrequently in the branch to the lower lobe. It is about twice as common on the right side as on the left. The bulbous end is generally directed towards the trachea. The surface is usually smooth and shiny, but may be nodular. An erroneous diagnosis of carcinoma was not uncommon in the past owing to differences of staining of certain of the constituent cells and their irregular distribution in the connective tissues. Metastases, however, are unknown. An adenoma often projects through the bronchial wall, giving it a dumb-bell or cottage-loaf conformation.

Clinical Features.—Often the earliest symptom is hæmoptysis, and this may be slight or profuse, since adenomata are very vascular and bleed easily. In other cases the tumour causes bronchial obstruction with resultant cough and wheezing, proceeding later to pulmonary collapse or bronchiectasis. Dry pleurisy may be an early result of infection, and at times pleural effusion or empyema may conceal the underlying cause.

Diagnosis.—Other causes of hæmoptysis must be considered, such as pulmonary tuberculosis, mitral stenosis, dry bronchiectasis or bronchial carcinoma. Pulmonary collapse may suggest an unresolved pneumonia. In cases of pleural effusion or empyema the diagnosis is liable to be overlooked. The injection of lipiodol or neo-hydriol, or tomography, will often reveal a blocked or deformed bronchus, but the diagnosis can only be established by microscopical examination of a portion of the tumour removed through a bronchoscope.

Prognosis.—This varies with the stage at which the diagnosis is established. If the condition is recognised early, and treated before the growth has extended outwards through the bronchial wall and before bronchial obstruction and septic infection have occurred, the outlook is favourable.

Treatment.—When the adenoma is recognised before secondary effects have developed, piecemeal removal through a bronchoscope, followed by radon application is often completely successful. There are, however, the

risks of hæmorrhage, primary and secondary, and of local recurrence, especially when the growth has extended outside the bronchus. Deep X-ray therapy has been recommended. If secondary bronchiectasis and fibrosis have occurred, lobectomy, or in rare cases pneumonectomy, may be necessary.

THE INFECTIVE GRANULOMATA

Syphilis.—During the secondary stage, a generalised hyperæmia of the bronchial mucous membrane may occur, giving rise to slight bronchial catarrh with the usual symptoms and signs, a condition that has been called syphilitic bronchitis. It is frequently beneficially influenced by anti-syphilitic treatment. In the tertiary stage, gummata may form in or near the large bronchi. They tend rather to fibrosis and contraction than to softening and ulceration, although the latter processes may occur. Contraction may lead to bronchial stenosis, with the symptoms and signs described below, or to extensive peribronchial inflammation and bronchiectasis. If the gummata extend into the lung, as may happen in rare instances, destructive lesions with cough, expectoration and hæmorrhage may result. This condition is more fully described in the section on pulmonary syphilis (see p. 1218).

Tuberculosis of the bronchi occurs as part of pulmonary tuberculosis and does not require separate description.

Leprosy.—The bronchi may be involved in this disease, with the production of cellular infiltration and even nodule formation. At first, these lesions may produce bronchitis, and they are progressive, leading to cough, expectoration, wasting and asthenia. The general clinical picture may simulate chronic pulmonary tuberculosis, from which it is distinguished by the presence of leprous lesions elsewhere, and the absence of tubercle bacilli from the sputum.

BRONCHIAL STENOSIS AND OBSTRUCTION

Obstruction of the main bronchi or of their subdivisions within the lungs may arise from causes within the bronchi or from conditions outside them, and these require separate consideration. It is important to emphasise the fact that in both conditions the symptoms differ according to whether the obstruction is sudden and complete, in which case collapse of the corresponding lung is the rule, or whether it is partial and more gradual, when bronchiectasis usually results. Obstruction of the smaller bronchi may result from spasm as in asthma (see p. 1148) or from disease as in small-tube and capillary bronchitis (see p. 1133).

(*a*) Internal Causes

These are most conveniently considered in two groups—(1) Foreign bodies; (2) those due to disease or cicatrisation of the bronchial walls.

(1) Foreign Bodies in the Bronchi

These usually gain access through the larynx and trachea by inhalation. Any inhaled foreign body that is small enough to pass down the trachea may

reach a main bronchus, more commonly the right, or if it is small it may pass into one of the secondary bronchi. It may at once become impacted, or be moved by cough, but unless it is expelled in this way, it is sooner or later drawn into the smallest bronchus that will receive it, and there becomes impacted.

The recorded varieties of foreign body thus reaching the bronchi are very numerous, but among the more common are pieces of bone, beads, pins, coins, ear-rings, studs, pencils, fruit stones, grains, grasses, beans, nuts, teeth and pieces of tonsil or adenoid growths after tonsillectomy. Even a living fish has been inhaled into a bronchus. Foreign bodies may reach the bronchi through a tracheotomy wound, or a gland may ulcerate into the lumen of a bronchus. Broncholiths and pneumoliths, calcareous particles originating in the bronchi and lungs respectively, may be inhaled into a bronchus instead of being expectorated.

Pathology.—The pathological changes resulting from a foreign body in a bronchus depend upon the nature of the foreign body, the duration of its stay, the size of the bronchus obstructed by it, and the degree of obstruction induced. If the foreign body is smooth and comparatively little septic, and if it be removed within 24 hours or so, complete recovery after a very mild local inflammatory reaction may be expected. If, on the other hand, the foreign body is rough, or soft and laden with septic organisms, acute pneumonic processes, often septic in character, may develop very rapidly. A soft type of foreign body may swell and completely obstruct the bronchus it reaches, leading to complete collapse of the corresponding lung area, often the whole or half of the lower lobe. If the stay of any foreign body is prolonged to days, weeks, months or longer, irreparable damage almost invariably results. The forms this may take are numerous. Collapse and septic pneumonia have already been mentioned. If the obstruction is partial, septic bronchitis, with stagnation of the bronchial exudate and pus behind the obstruction, leads in turn to peribronchitis, bronchiectasis and fibroid induration of the corresponding lung area. In other cases gangrene of the lung results. Not infrequently an empyema may occur and the foreign body may be found in the empyema cavity. Suppuration round a foreign body may lead to localised intrapulmonary suppuration or abscess. Simple bronchial obstruction, uncomplicated by sepsis, may lead to bronchiectasis, owing to the resultant lowering of intrapleural pressure.

Symptoms.—During the passage of the foreign body through the larynx and trachea urgent symptoms may occur which leave no doubt as to what has happened; but this is not invariable, and the patient may not be sure whether he has inhaled or swallowed it. In any case, after a bronchus has been reached, there may be a latent period which engenders a sense of false security and leads to delay in treatment. In most cases pain, discomfort and cough develop rapidly. The cough may lead to the expulsion of the foreign body, or may cause dyspnœa if it forces it up to the larynx. The cough soon becomes noisy, often paroxysmal, and if local septic changes are set up expectoration occurs, sometimes mucoid and copious, at others muco-purulent. Hæmoptysis is not uncommon. Pain may be absent, but is often severe. The temperature is generally normal for the first few hours, but soon rises, especially if bronchitis, pneumonia or broncho-pneumonia

develops. The further symptoms are those of the reactive changes and complications which ensue.

The physical signs naturally depend upon the bronchus affected and upon the degree of obstruction. They are at first those of deficient air entry. The affected side may show less movement, and there may be some recession of the lower intercostal spaces in young people. If a large bronchus is involved and collapse results, there is some displacement of the heart to the affected side. Vocal fremitus may be diminished or absent, the percussion note impaired, and the breath-sounds and voice-sounds weak or absent over the whole or part of one lung, almost invariably the lower lobe. When bronchiectasis, empyema or other conditions develop, their characteristic signs become apparent.

Complications and Sequelæ.—These have been enumerated in describing the pathological results. Sometimes septic meningitis or cerebral abscess develops.

Course.—Spontaneous relief may occur in two ways, either by the foreign body being coughed up, as may happen within a few hours or days or after an interval of months or years, or the foreign body may track through the lungs and pleura, and be discharged in an abscess bursting through the chest wall. In both cases, if an interval of more than days occurs, irrecoverable damage may have resulted. Apart from these occurrences and from successful treatment the course is very variable. Death may occur quickly from some of the septic complications, or after a longer or shorter interval from bronchiectasis, gangrene or cerebral abscess.

Diagnosis.—The history of disappearance of some article from the mouth in the act of laughing, breathing, yawning, coughing or sighing, should always arouse suspicion of an inhaled foreign body. If signs indicating bronchial obstruction are found, the diagnosis is almost certain. In every suspicious case radiograms of the chest should be taken in two different directions, in case the shadow may be merged in that of the scapula or of the ribs. The possibility of a foreign body should always be borne in mind in cases of unilateral basic bronchiectasis, especially if no obvious cause can be found. When such unilateral lung signs develop after an anæsthetic, or after operations on the mouth or naso-pharynx, the possibility of some inhaled material should always be remembered.

Prognosis.—This is grave unless the foreign body is removed within 36 hours, owing to the various dangerous complications that may ensue. Excluding the few cases in which cure occurs by spontaneous discharge of the foreign body, about 50 per cent. of cases left untreated die within 1 or 2 years.

Treatment.—This consists in removal, if practicable, as soon as possible after the diagnosis is established. If the foreign body is in a main bronchus or one of its principal divisions it can usually be removed by means of the bronchoscope and appropriate forceps. In case of failure the question of pneumotomy may have to be considered. If this is decided on, every effort must be made to localise the foreign body by X-ray examination. If intrapulmonary or pleural suppuration has occurred, this must be dealt with surgically, and sometimes the foreign body can be removed at the same time. The medical treatment of the cases consists in that of the various conditions resulting.

(2) Obstruction or Stenosis from Disease or Cicatrisation of the Bronchial Wall

Ætiology.—Primary bronchial new-growths, including adenoma, columnar-celled carcinoma, oat-celled tumour and squamous-celled carcinoma lead to bronchial obstruction at an early stage. These conditions produce symptoms and signs practically identical with those of new-growths in the lung (see p. 1220).

A plug of mucus or a blood clot may cause temporary obstruction of a large bronchus.

The causes of cicatrisation are those leading to ulceration of the bronchial wall, with subsequent healing, such as syphilitic processes in and around the bronchi, ulceration from injury produced by a foreign body or in its removal, or by the inhalation of severe irritants. The fibroid variety of tuberculosis may also produce it.

Pathology.—The stenosis may occur in one of the main bronchi, or in one passing to a lobe or to part of a lobe. At first partial, it may progress until the lumen is almost completely occluded at one point. The changes occurring in the lung beyond the obstruction vary with its degree. At first there is retention of secretion in the bronchi, and air may be forced past the obstruction in inspiration, but not expelled during expiration, producing emphysema, with gradual bronchial dilatation. When the obstruction is more complete the air is absorbed, the lung tissue gradually becomes fibrotic, and the bronchi dilate further.

Symptoms.—Cough, not infrequently of paroxysmal character, is an early symptom and is usually a continuation of that caused by the primary condition. It may be dry or associated with mucoid sputum, sometimes blood-streaked. The expectoration may cause dyspnœa, by obstructing the narrowed bronchus. If bronchiectasis develops, the sputum usually becomes fetid.

The physical signs are those of collapse of a part of the lung and are progressive. Local limitation of movement and flattening, with displacement of the heart to the affected side, may be apparent on inspection. The vocal fremitus is diminished, the percussion note, impaired at first, may progress to complete dullness when fibrosis develops. The breath-sounds are weak or even absent, and the voice-sounds diminished. In the early stages a bronchial stridor may be audible. Compensatory emphysema of the adjacent healthy lung tissue often develops.

Complications.—These are similar to those in stenosis from a foreign body, notably fibrosis and bronchiectasis.

Course.—Unless the primary condition causing the stenosis is one which can be arrested by treatment, the condition is progressive, and eventually the area of lung beyond the obstruction becomes permanently functionless.

Diagnosis.—Bronchial cicatrisation must be differentiated from obstruction due to extrabronchial causes, such as pressure from new-growths, aneurysm and the other mediastinal conditions mentioned in the section below. The history, the physical signs and examination by X-rays and, if necessary, by the bronchoscope may help in distinguishing. The Wassermann reaction should be investigated in every case where the stenosis is proved to be of intrabronchial origin.

Prognosis.—This varies with the cause. It is most favourable in cases due to syphilis submitted to treatment at an early stage.

Treatment.—Vigorous anti-syphilitic treatment should be employed in cases due to syphilis. In other cases the treatment is to relieve symptoms by appropriate measures.

(*b*) External Causes

These may be subdivided into—(1) *Mediastinal conditions*, chiefly enlargement of the bronchial or mediastinal glands from tuberculosis, Hodgkin's disease or malignant growth, aneurysm of the aorta, mediastinal abscess, pericardial effusion and œsophageal new-growths. (2) *Intrapulmonary causes*, generally primary or secondary new-growths.

Symptoms.—These are practically identical with those just described, but in addition there are those of the condition causing the pressure.

Diagnosis.—This has been discussed in the previous section. The bronchoscope should not be employed where there is any suspicion of an aneurysm.

Prognosis.—This is extremely unfavourable, except in cases due to tuberculous glands and pericardial effusion, and in some cases of mediastinal suppuration.

Treatment.—This can only be palliative in the majority of cases. Useless cough may be checked by a sedative linctus of diamorphine (heroin) or morphine. Dyspnœa when due to spasm may be lessened by inhalations of creosote and spirits of chloroform, or by administration of oxygen. Pain may be relieved by aspirin or other analgesic drugs.

ASTHMA

The term asthma has been loosely employed to denote any form of dyspnœa of expiratory type occurring in paroxysms. For all conditions other than that now to be described some descriptive qualification should be employed to avoid confusion.

Asthma or true spasmodic asthma is a paroxysmal affection, occurring most frequently in patients of neuropathic inheritance. It manifests itself in attacks of severe expiratory dyspnœa due to excessive vagal discharges, set free by peripheral irritation, chemical agencies or cerebral influences.

Ætiology.—Probably no other disease shows such a varied and complex causation, but studies of idiosyncrasy and anaphylaxis have served to explain many of the obscurities.

Predisposing causes.—Age.—The first attack may occur at any age, even as early as the period of the first dentition. The majority of cases begin before the age of 25.

Sex.—Asthma is generally stated to be nearly twice as frequent in the male sex as in the female.

Heredity.—Asthma certainly runs in families. The heredity is not always direct, the nervous instability sometimes being evidenced in other generations by migraine, epilepsy or hysteria. The view that hypersensitiveness to certain proteins is inherited is now discredited, and it is believed that an unduly irritable bronchial centre is the factor transmitted by heredity.

Other diseases.—Gout and syphilis are said to predispose to asthma. Bronchitis not infrequently leads to paroxysms in patients with asthmatic tendencies. Tuberculosis of the lung occasionally induces it, but here again it is probably in patients with the asthmatic diathesis.

Climate and locality.—Asthmatics seem very sensitive to both of these, but no general relationship can be proved, as the effects are most variable. Some patients are better in dry, others in damp, foggy climates, and in regard to locality each patient is a law to himself.

Conditions of the nose and naso-pharynx.—Nasal obstruction from swelling of the turbinates, deflection of the septum, spurs and polypi, and conditions of the naso-pharynx, such as adenoids and enlarged tonsils, undoubtedly predispose to asthma, and may also be exciting causes of the actual paroxysm.

Exciting causes.—Chemical substances.—The emanations from certain animals may be the determining cause. The best known of these are the horse and cat, but rabbits, hares, guinea-pigs, deer, dogs and monkeys may have a similar effect. Even human hair appears capable of discharging the paroxysm. The dust from some substances, such as corn, rice or oats, the smell of certain drugs, such as ipecacuanha, and the scent and the pollen of grasses and flowers may act in a similar fashion, as also may articles of diet, and many drugs. This factor in causation has attracted much attention —in this country by Freeman, Coke and Bray, and in America by Walker. It is claimed that at least 50 per cent. of asthmatics show hypersensitiveness to various protein antigens obtainable from animals, grains, bacterial bodies, foods and drugs, and over a hundred are now available for routine testing of these patients. The analogy with the causation of hay fever and paroxysmal sneezing is obvious. This group has been referred to as "allergic" asthma.

Peripheral irritation.—As already mentioned, irritation of the nose, naso-pharynx and bronchi may be asthmogenic in those of asthmatic tendency.

Gastro-intestinal disturbance.—This is well recognised as a cause, and most asthmatics find by experience the penalties of a heavy late meal and of indigestible articles of diet. It is possible that actual metabolic errors may be a factor, as in the so-called "week-end asthma," due to altered conditions of diet and exercise at this period.

Genito-urinary conditions, particularly in women, notably ovarian or uterine disorders, sometimes act in inducing asthma.

Cutaneous.—Asthmatics are peculiarly liable to urticaria and eczema, although these conditions usually alternate with the asthmatic attacks.

Nervous factors.—Fatigue, emotion and nervous shock may precipitate an attack. This factor cannot be ignored, even in cases due to protein hypersensitiveness, as is shown by a well-known case in which a patient susceptible to roses developed asthma when handed an artificial rose.

Pathology.—Numerous theories have been propounded to explain the asthmatic paroxysm. Among these may be mentioned vascular turgescence of the bronchial mucous membrane, spasm of the bronchial muscle and increased secretion of the mucous glands. Spasm of the diaphragm or of the inspiratory muscles has also been suggested. That bronchial spasm plays the major part seems to have been established by the experiments of Brodie and Dixon, and this view is strongly supported by their observations on the effects of drugs on the bronchial musculature. Muscarine, pilocarpine and physostigmine produce bronchial constriction and asthmatic symptoms

in animals, while atropine, hyoscyamine and chloroform abolish these effects.

There can now be little doubt that the broncho-constrictor fibres of the vagus are the channel by which the impulses discharging the asthmatic paroxysm reach the bronchi, although the possibility that impulses leading to vaso-dilatation and to increased bronchial secretion are also concerned, must be admitted.

ANAPHYLAXIS.—The important part played by extraneous proteins in the genesis of asthma and the obvious analogy between the asthmatic paroxysm and the symptoms of anaphylactic shock have suggested that in many cases, if not in all, asthma is an anaphylactic phenomenon. Evidence is accumulating in support of this view. It has been shown that the lungs of the guinea-pig killed in anaphylactic shock show extreme constriction of the bronchioles. Asthmatics are well known to show anaphylactic tendencies, and especial care in the administration of antitoxic serums is necessary with them. It is of some interest to note that the Eppinger and Hess group of vagotonics show urticaria, dermatographia, eosinophilia and liability to anaphylactic shock, all conditions which occur in asthmatics. It is tempting, therefore, to assume that the foreign protein or toxin produces the asthmatic attack by inducing vagotonicity. Lastly, the observations of Freeman, Coke and the American workers have demonstrated the cutaneous hypersensitiveness of many asthmatics to special foreign proteins. Further research is needed before it can be accepted that anaphylaxis accounts for all cases of asthma, but it is almost certainly an important factor in many.

Symptoms.—The asthmatic paroxysm most commonly commences about 2 a.m. or later, but it may sometimes develop in the daytime. There are often preliminary indications some hours beforehand, constituting the "asthmatic aura." These include restlessness, irritability, mental exaltation, less frequently depression, itching of the nose or chin, flatulence or polyuria. Some attacks are ushered in by coryza. Such warnings are not constant, and the sufferer usually wakes from sleep with a feeling of suffocation. In early attacks great restlessness, anxiety and alarm occur. The difficulty in breathing and the sense of suffocation increase; the patient sits up in bed, or gets up to throw open the window, and fixes his arms to bring into action all possible muscles of respiration. Respiration, although laboured and difficult, is often slow, inspiration being short while expiration is greatly prolonged. Both are accompanied by loud wheezing sounds, audible at a distance from the chest. The patient appears pale, but the lips are dusky and the expression is anxious and distressed. The jugular veins are distended and prominent. The accessory muscles of respiration are seen to be in violent action, notably the sterno-mastoids, scalenes and pectorals. The skin is moist and there may be marked sweating. The chest is much distended, and at each violent attempt at inspiration very little further enlargement occurs, while there is often sucking-in of the supra-clavicular and lower costal regions.

Percussion reveals marked hyper-resonance and encroachment on the cardiac and hepatic dullness. On auscultation inspiration is short and high-pitched, expiration very prolonged, and both are obscured by abundant sonorous and sibilant rhonchi, and later by bubbling râles at the bases. The

pulse is small, quick and sometimes irregular. There is usually marked epigastric pulsation. A differential blood count during an attack may show an eosinophilia of as much as 35 per cent. Cough does not develop until late in the paroxysm, and is quickly followed in many cases by the expectoration of small pellets, called "perles" by Laennec, and often likened to boiled sago or tapioca. These were carefully studied by Curschmann, and when examined on glass on a black background, prove to consist of a central highly refractive mucinoid coil, with masses and threads of mucin wrapped spirally around it. Microscopically leucocytes, mostly eosinophils, may be seen entangled in the mucus. The sputum frequently contains Charcot-Leyden crystals, which are now accepted as spermin phosphate. With the onset of expectoration the dyspnœa quickly lessens, and the attack subsides. The patient often passes a large quantity of pale urine and then may sleep until morning, awaking in apparent comfort. More frequently he appears pale, tired and anxious.

Course, Complications and Sequelæ.—Such an attack may last from a few minutes to several hours, and may remit and then return. When the spasm is very severe and prolonged into hours, with little or no remission, the condition is often termed "status asthmaticus." The patient may be extremely ill, and death may occur unless the attack remits spontaneously or as a result of treatment. More often the attacks recur at the same time each night for a considerable period extending to weeks, and then pass off, after which the patient may enjoy a period of freedom of weeks or months. The intermissions may become shorter with successive attacks, and increasing emphysema may develop. This in turn leads to secondary bronchitis, which persists, together with some degree of permanent œdema of the bases. Later still the cardio-vascular changes incidental to emphysema occur as sequels, namely, engorgement of the right heart, tricuspid regurgitation, venous stasis, ascites and œdema. Chronic asthmatics frequently present a characteristic appearance. Of thin build, with sallow complexion, anxious expression and nervous manner, they often have a long neck, high straight shoulders, and a forward stoop. Asthma necessarily imposes limitations upon those who suffer from it at all severely, although many asthmatics lead active, useful lives in spite of their disease.

Diagnosis.—This involves the differentiation from other forms of dyspnœa, particularly those of spasmodic expiratory type. The chief forms of paroxysmal expiratory dyspnœa are:

1. *Bronchial asthma or spasmodic dyspnœa complicating chronic bronchitis and emphysema.*—This condition is sometimes a late result of true asthma, but may occur independently. The dyspnœa is more persistent and is more definitely related to the bronchitic attacks, being therefore more common in the winter.

2. *Cardiac dyspnœa or cardiac asthma.*—This, like true asthma, is usually nocturnal, but the signs of failure of compensation in association with valvular or myocardial disease usually make the nature of the dyspnœa clear.

3. *Uræmic dyspnœa or renal asthma.*—This is also not infrequently nocturnal and may be almost indistinguishable from true asthma. Examination of the urine, the urea and non-protein nitrogen content of the blood, usually enable the distinction to be made with certainty. Cardio-vascular changes with high blood pressure are frequently but not invariably present.

4. *Hay asthma* is probably only a severe form of hay fever and is to be regarded as a variety of true asthma.

5. *Pulmonary tuberculosis may be associated with asthmatic dyspnœa.*—The differentiation may not be easy during the attack, but the persistence of apical signs in the interval may give a clue. It is a wise precaution to examine the sputum for tubercle bacilli in all cases of asthma. A low blood pressure in an asthmatic should also arouse suspicion of tuberculosis.

The dyspnœa of laryngeal or tracheal obstruction and of mediastinal pressure can usually be recognised by the fact that it is chiefly of inspiratory type, and may be associated with stridor, instead of wheezing. In all cases of doubt the chest should be examined with the X-rays to exclude aneurysm or new-growth.

Prognosis.—When the disease starts in childhood or in early adult life it may stop spontaneously or be relieved permanently when some causal condition is discovered and treated. During a severe attack the aspect of the patient may be so alarming that a fatal issue may seem imminent, yet death rarely occurs. In chronic cases, the ultimate prognosis is made more serious by the complicating emphysema and bronchitis, and in spite of popular belief, the asthmatic has less than the normal expectation of life.

Treatment.—(*a*) *During the attack.*—The list of anti-spasmodic drugs and measures employed is a long one, and it is impossible to foretell which will be efficacious, for asthmatics vary as widely in their response to drugs as they do in regard to asthmogenic causes. Drugs may be administered for this purpose by inhalation, by nasal sprays, by the mouth or by hypodermic injection. Adrenaline hydrochloride, in doses of 2 to 5 minims of a 1 in 1000 solution hypodermically, may act with dramatic efficacy if administered sufficiently early, but it should be given cautiously to elderly asthmatics. It may also be combined with pituitary extract, as in the special preparations evatmine, pitrenalin and asthmolysin. In status asthmaticus, the procedure suggested by Sir Arthur Hurst may give relief. A syringe of 1 c.c. capacity is filled with adrenaline solution 1 in 1000. This is slowly injected over a period of several minutes to half an hour or until the spasm relaxes. Ephedrine hydrochloride, in tablets of gr. $\frac{1}{4}$ to $\frac{1}{2}$, has proved itself a useful substitute for adrenaline in some cases and can be given by the mouth. Pseudo-ephedrine in doses of $\frac{1}{2}$ to 1 grain is often helpful where ephedrine fails. Ephetonin, a synthetic preparation of similar character, is also sometimes employed. Adrenaline often proves helpful as a nasal spray, especially in combination with chloretone. A weak solution of cocaine and atropine in an oily excipient has been much employed as a nasal spray, but it is not devoid of risk if used indiscriminately. The fumes of burning nitre paper, or of a powder composed of tobacco, stramonium and nitre, sometimes help to relieve the distress, but they should be avoided in cases with bronchitic complications. Smoking a cigarette or a cigar may be helpful in patients who do not smoke habitually; others are helped by cigarettes containing stramonium. Inhalations of amyl nitrite, ethyl iodide or chloroform may be tried in some cases. Various drugs have been employed, of which potassium iodide and bicarbonate with tincture of stramonium, hyoscyamus, lobelia or belladonna are the most useful. Twenty minims of liquid extract of grindelia every 20 minutes for three doses have been found useful in some cases. Other drugs which have been recommended are chloral hydrate, phenacetin and the other coal

tar antipyretic drugs, elixir of caffeine tri-odide (eupnine) in 60 minim doses, and an emulsion of benzyl benzoate, 120 minims every 2 hours. Other measures include drinking a cup of strong coffee, the application of a mustard leaf over the sternum, and placing the feet in hot water and mustard. In very severe cases, if all else fails, it may be necessary to inject morphine or diamorphine (heroin), but this should only be done after careful consideration, owing to the danger of inducing habit particularly with heroin. It is especially dangerous in cases of status asthmaticus.

(*b*) *Between the attacks.*—The greatest care should be taken to discover and deal with any predisposing or exciting cause. The patient should live in that locality which his experience shows to be most suitable for him, and at present no rules can be formulated in advising on this matter.

Diet requires careful consideration. Any article of diet to which the asthmatic is susceptible should be entirely eliminated, and only the lightest of meals should be taken after midday. Dextrose has proved to be helpful in some cases of asthma in childhood. It is recommended to give 3 teaspoonfuls in lemonade or orange juice 3 times a day, with extra sugar and sweets at meals. Alkalis may also be given at the same time. Fatigue, overwork and emotional stress are to be avoided. Care should be taken to see that the bowels act efficiently. The general health should be maintained by every possible means. Arsenic may be given by the mouth or intravenously or intramuscularly as sodium cacodylate (gr. $\frac{3}{4}$ in min. 15 sterile water). When the patient is having a series of attacks, iodide of potassium with one or more of the anti-spasmodic group of drugs such as stramonium, lobelia, belladonna and grindelia, may be given regularly with great benefit. Any local source of irritation in the nose or naso-pharynx should be dealt with adequately. Sometimes touching the nasal septum with the galvano-cautery may alone be efficacious. In cases complicated by bronchitis, the sputum should be examined bacteriologically, and a vaccine may be made from the predominating organisms, but small doses and very gradual increments should be employed, since asthmatic patients are frequently hypersensitive to vaccines. If these prove to be *Micrococcus catarrhalis*, or Friedländer's pneumobacillus, great benefit may result, but the patient should be told that the vaccine can only help the asthma by lessening the accompanying catarrh. Some cases associated with marked emphysema obtain considerable relief from compressed air baths, at first on alternate days, then daily, the course extending to 1 or 2 months.

Careful investigation of the question of protein hypersensitiveness should be undertaken, and the method of testing by means of the cutaneous application of various antigens is worth a trial. For this purpose, the particular protein antigen, or a series of such antigens, may be applied to the skin of the forearm in the form of powder, solution or paste, and superficial scarification is then effected by means of a sterile needle or scalpel. A positive reaction is shown by the development of an urticarial wheal surrounded by a hyperæmic area. A control scarification with normal line or a paste free from protein should be made at the same time. A sitive result may be expected in about 50 per cent. of asthmatic patients. such a condition is established to one or more such substances, they should be avoided if possible; if not, the methods of desensitisation may be tried, but the results are frequently disappointing. The specific antigen

may be employed in very minute doses by injection, starting, for example, with 1 minim of a $\frac{1}{100,000}$ solution and gradually increasing. Peptone given by the mouth or by hypodermic injection is sometimes employed as a shock desensitising agent.

A variety of "shock" treatment which has given good results is the intramuscular injection of sulphur oil (*huile soufrée*), 0·03 gramme in 1 c.c. This is given in doses up to 1 c.c. once or twice weekly over a period of weeks or months.

A gold salt, allochrysin, has been given intramuscularly in doses of 0·05 gramme, followed in a week by 0·1 gramme, and then, if tolerated, up to 0·2 gramme at weekly intervals till a total amount of 2 grammes has been given.

Breathing exercises of expiratory type such as those recommended by the Asthma Research Council are often of great value.

BRONCHIECTASIS

Definition.—Bronchiectasis is a condition of permanent dilatation of one or more bronchi. When it occurs in the finer divisions it is sometimes described as bronchiolectasis.

Ætiology.—Bronchiectasis is invariably secondary, and may result from disease of the bronchi, the lung parenchyma or the pleura. Even the rare congenital cases are probably consequent on malformation, atelectasis or intra-uterine disease.

1. The bronchial conditions which may progress to dilatation are bronchitis, and any affection leading to partial bronchial obstruction, such as inhaled foreign body, tumour (simple or malignant), stenosis from cicatrisation and external pressure from new growth or aneurysm. Localised pulmonary collapse thus induced seems to be the commonest antecedent condition. In children, measles and whooping-cough are not uncommon causes, especially when they follow one another in rapid succession, although either alone, if severe, may lead to it.

2. Conditions of the lung parenchyma which may cause bronchiectasis are unresolved pneumonia, broncho-pneumonia, collapse, syphilis and tuberculosis. Syphilis is rare and usually acts by leading to bronchial obstruction or stenosis. Fibroid tuberculosis is a common cause, but the clinical manifestations are as a rule masked by the primary condition. The pulmonary complications of influenza are not infrequently followed by bronchiectasis.

3. The pleural conditions which are followed by bronchiectasis are those which lead to pleural adhesion and those which are associated with pulmonary fibrosis, notably chronic pleural thickening, or empyema leading to prolonged or permanent collapse of the lung.

In a lesion with such diverse antecedents the age relations are necessarily indefinite. It may occur at any age, but is commonest in the third and fourth decades. It frequently commences in childhood, although the characteristic clinical manifestations may not develop until adult life.

Sex.—In most recorded statistics there is a striking preponderance in the male.

Social state.—It is noteworthy that bronchiectasis in its more severe form is more common in the poor than in the well-to-do.

Pathology.—Four factors in the pathogenesis of bronchial dilatation have to be considered. (1) The most important is the localised collapse which leads to secondary bronchial dilatation. (2) Weakening of the bronchial walls. Most of the conditions preceding bronchiectasis tend to induce severe bronchitis and peribronchitis, and thus render the walls more yielding. Where stagnation of secretion occurs, septic and putrefactive organisms develop, producing tryptic ferments which may act injuriously upon the lining membrane. The importance of the infective factor has been stressed by Moll. (3) Increased pressure on the walls thus weakened is the determining factor. This is generally expiratory in origin and due to the strain of cough. The actual pressure of secretion accumulating behind an obstruction may promote yielding of the bronchial walls. In cases of bronchiectasis following on collapse of the lung the force of inspiration has been regarded as contributory, but this is doubtful and in any case is less important than the expiratory strain of cough. (4) The fourth possibility is the traction exerted upon the walls of the bronchi by contracting connective tissue in the surrounding fibroid lung. This obviously postulates the existence of pleural adhesion, which is not invariably present. While this must be admitted as a possible contributory factor, its importance is certainly less than that of the preceding ones.

Congenital bronchiectasis is a pathological rarity and may be confused with congenital cystic disease of the lung (see p. 1222). It is usually unilateral, and the bronchi involved are of small size, although in some cases the lung may show a large central cavity, with smaller spaces around it. Bronchiolectasis is also more of pathological than of clinical interest It occurs chiefly in children, as the result of acute broncho-pneumonic processes. It is said sometimes to follow influenza and possibly tuberculosis. The lung has a peculiar spongy appearance, to which the name "honeycomb" has been applied.

Bronchiectasis of the larger tubes may be either cylindrical or saccular. In the former condition several of the bronchi are more or less uniformly dilated, and when opened out they appear like the fingers of a glove. Sometimes the dilatations are fusiform, at others they show a beaded arrangement, described as moniliform. These forms of dilatation are usually associated with emphysema and chronic bronchitis. Saccular bronchiectasis is generally localised and may be found in any part of the lung, but is most common in the lower lobes and near the base. This is partly due to the fact that the antecedent processes fall with special stress on the bases of the lung, and partly to the influence of gravity in leading to retention of secretions in these parts. Although it may be unilateral in origin, it often spreads and may involve both bases or even all the lobes. There may be one large irregular cavity, or a series of smaller globular dilatations involving the whole or part of the walls of one or more bronchi. The cavities are usually filled with the fetid secretion, to be described under expectoration. When this is washed away the walls are found to be thin, smooth and formed of thinned-out mucous membrane. In places this may have ulcerated, owing to the tryptic action of the secretion, and the lung tissue is thus exposed. An abscess may then form, and an aneurysm sometimes develops, as in a tuberculous cavity. The openings of the smaller bronchi, derived from the dilated bronchus, can often be recognised in its walls. In doubtful cases the

histological demonstration of cartilage and muscle in the walls establishes the bronchial origin of a cavity. The surrounding lung tissue is usually airless and fibroid, and sometimes is almost of leathery consistence. Occasionally, however, it is emphysematous, congested or pneumonic. In the great majority of cases there is a dense pleural adhesion over the area of lung involved.

Other morbid conditions found post mortem include lardaceous disease, gangrene of the lung, empyema, pyo-pneumothorax, suppurative pericarditis and cerebral or spinal cord abscess. Owing to the obstruction of the pulmonary circulation which may result, engorgement and dilatation of the right side of the heart, tricuspid regurgitation and the results of systemic venous stasis are often found.

Symptoms.—The onset is usually insidious, the symptoms developing during the course, or as a sequel, of one of the acute or chronic affections mentioned above. In some few cases, however, they develop rapidly in patients previously in good health. This is particularly the case where bronchiectasis results from an inhaled foreign body or after general anæsthesia, and a rapid onset should lead to the suspicion of this. The cough in well-developed cases is somewhat characteristic and occurs in paroxysms. These are frequently induced by change of posture—for example, bending forward or lying down. They occur with special frequency on rising, and are usually associated with the expectoration of large quantities of sputum, due to the overflow of the secretion, accumulated in the cavities during the night, into a sensitive or relatively healthy bronchus, which excites cough reflexly. They also occur on retiring to bed and at long intervals during the day. The sputum frequently amounts to as much as 20 or 30 ounces in the 24 hours. It is generally extremely fetid, although in the earlier stages it is not invariable. The patient's breath is often also malodorous, and the stench may pervade the room or even the house in which he lives, although it is not persistent. The patient is himself much distressed by the unpleasant character of the sputum, of which he is, as a rule, acutely conscious. On standing in a glass vessel it can be seen to settle into three layers—a surface scum of light frothy mucus, an intermediate stratum of thin, turbid, greenish fluid, and a deep layer of brownish colour consisting of muco-pus, bacteria, anaerobes, spirochætes and putrefactive products, including foul-smelling organic acids. Fetid yellow bodies called Dittrich's plugs can usually be found in the deep layer. Elastic tissue is only present when erosion of the wall has occurred. Hæmoptysis is not infrequent, and may occasionally be fatal. It may be the first and only symptom in some cases, which are referred to as dry or silent bronchiectasis. Dyspnœa is not, as a rule, apparent unless the condition is widespread, or unless the pulmonary or cardiac complications are present. The general condition of the patient is at first but little affected, and there may be no fever for long periods. As the disease progresses, lassitude, anorexia and some wasting slowly develop, while bouts of fever occur, due to retained secretions or to some complication.

Physical signs vary with the extent and degree of dilatation, and also with the amount of secretion present. In the early stages there is at most slight dullness at one base, with diminished air entry, peculiar sticky, "leathery" râles, and diminished vocal resonance. When bronchiectasis is well developed the signs are almost characteristic. The patient may appear well nourished and of good colour, although on cold days, especially

in children, duskiness or cyanosis is often noticeable. There is well-marked clubbing of the fingers, generally of drum-stick character, and pulmonary osteo-arthropathy, involving many joints, sometimes develops. There may be localised flattening or retraction of the chest wall over the affected area, with diminished movement, and the heart is drawn over to this side. The remaining signs vary with the state of the cavity. If this is full, there is diminished vocal fremitus, dullness and weak or absent breath-sounds and voice-sounds. If the cavity is empty or partly empty, the vocal fremitus is increased, the percussion note is boxy or dull, while the breath-sounds are bronchial or cavernous. Adventitious sounds are then generally audible, the most characteristic being sharp metallic or "leathery" râles. Bronchophony and pectoriloquy are marked, and occasionally the "veiled puff" of Škoda can be heard. Signs of bronchitis are often apparent in the adjacent lung tissues; compensatory emphysema may be demonstrable in the unaffected parts of the lung, and on the opposite side. X-ray examination before and after the injection of lipiodol or neo-hydriol serves to define the extent of the disease and the degree of fibrosis. Tomography may also be useful.

Complications and Sequelæ.—The chief pulmonary complications are septic broncho-pneumonia, gangrene and abscess. The pleura may become involved, giving rise to dry pleurisy, which sometimes progresses to empyema and rarely to pyo-pneumothorax, while in other cases pleural adhesion and contraction result. Septic pericarditis may develop and prove fatal. Septicæmia and pyæmia sometimes occur as terminal results. Cerebral abscess constitutes a serious and somewhat common complication, and may be found in the frontal, parietal or temporal regions, the cerebellum or cord. Occasionally multiple abscesses form. Lardaceous disease sometimes develops, especially in the liver, kidneys and intestines.

Course.—This is progressive, but is often slow unless fever or complications develop, though the morbid process may eventually involve the other lung. The sputum at first may be simply purulent, then becomes unpleasant and finally fetid. The disease may start in childhood and not lead to death until well on in adult life. The course is slower in cases due to bronchitis and fibroid lung conditions than in those due to foreign bodies, new growths or aneurysm.

Diagnosis.—In well-developed basic cases this is, as a rule, easy. The history of cough, influenced by posture and associated with copious sputum, is suggestive, especially when variable physical signs are observed. The development of the characteristic sputum with these signs renders the diagnosis almost certain, and the X-rays usually serve to confirm. Radiological investigation after an intra-tracheal injection of 10 to 20 c.c. of lipiodol or neo-hydriol, through the crico-thyroid membrane or between two rings of the trachea, under local anæsthesia, or with care directly between the vocal cords, has greatly facilitated the diagnosis of bronchiectasis. Franklin has recommended the nasal route for the introduction of the lipiodol. One nostril, the oro-pharynx and the larynx are cocainised, then a gum-elastic catheter is passed along the floor of the nose into the larynx. Some cocaine is injected down the catheter and then the lipiodól follows. An attempt should be made to direct the lipiodol towards the affected side by turning the patient towards that side. The injection should be carried out in the X-ray room and the patient instructed to restrain cough if possible until the films have

been taken. The pictures obtained are strikingly characteristic and of great value. In cases with less characteristic symptoms and signs the distinction has to be made from chronic bronchitis, especially the fetid variety, pulmonary tuberculosis, gangrene or abscess of the lung, and fetid empyema. The distinction from chronic bronchitis may be difficult, especially in the early stages when the sputum is not fetid, but the paroxysmal cough, the copious expectoration with signs including bronchial breathing and sticky râles at the base, may be strongly suggestive. In fetid bronchitis the fœtid sputum is not constant, and the cough and sputum may occur only during exacerbations of the bronchitis. Pulmonary tuberculosis may give rise to difficulty, particularly in cases of apical bronchiectasis. Repeated examinations for tubercle bacilli and also for elastic tissue in the sputum should be made. The history, the mode of spread, and X-ray examination may all assist. It should be remembered that the two conditions may coexist and, this may be suspected in some cases of fibroid tuberculosis with basic excavation. Abscess and gangrene of the lung have a more acute onset and course, but the chronic cavities left by these conditions may give rise to difficulty. In such cases the history may be an important aid in diagnosis. In fetid empyema rupturing through the lung, particularly when of interlobar origin, the patient is generally acutely ill, there may be a history of pleurisy at the onset and possibly some evidence of mediastinal pressure or cardiac displacement. The rare condition of congenital cystic disease of the lung may give rise to some difficulty (see p. 1223).

Prognosis.—This varies with the cause. If due to aneurysm or growth, the duration is determined by these conditions. Bronchiectasis induced by a foreign body is generally permanent, even when the latter is removed, but it is not progressive. If the foreign body is not removed, complications generally supervene, and the course may be rapid. In bronchiectasis due to bronchial or pulmonary disease the course may extend into years, particularly if treatment is followed strictly, but sooner or later toxæmia and general or local complications supervene, with the result that the duration of life is inevitably considerably shortened.

Treatment.—Prophylactic treatment in cases of chronic bronchitis, delayed resolution in pneumonia and other conditions tending to fibrosis is of the utmost importance. This comprises respiratory exercises, climatic treatment, inhalations and vaccines.

The medical treatment of bronchiectasis consists in measures to promote the general health and well-being of the patient, to secure efficient emptying of the cavity, and to lessen or control the putrefactive processes occurring in it. The first of these involves a careful mode of life, adequate rest and change, a good and digestible diet, and medicines such as cod-liver oil, iron, quinine, strychnine or arsenic. The evacuation of the cavity may be promoted by postural methods, such as bending over the edge of the bed or stooping forwards. This can now be effectively secured by treating the patient on a Nelson bed. By X-ray and iodised oil (lipiodol) the exact position of the cavities in relation to the trachea can be determined, and the patient placed in the position best adapted to secure effective drainage. Expectorants, especially of antiseptic character, may be given, such as creosote, terebene, tar preparations, balsam of tolu or Peru, compound tincture of benzoin or the benzoates. If the sputum is tenacious, or if much bronchitis coexists iodides

and alkalis may be given in an ordinary expectorant mixture. To lessen the fetor, creosote is most frequently given in perles of 3 to 5 minims three times a day after food, or in an emulsion with cod-liver oil. Guaiacol carbonate and other creosote derivatives may also be tried. Syrupus allii, in 60 minim doses, is sometimes given, and is of value; but it is not always well tolerated by patients on account of its taste and tendency to repeat. Although these drugs are helpful, the amount of antiseptic reaching the cavity by the blood must necessarily be small. Attempts to secure more direct application by intratracheal injection and by inhalation have been made. The former method is now seldom used.

For inhalation purposes, solutions of volatile antiseptics are employed on a Burney-Yeo mask, such as creosote, terebene, menthol or eucalyptol in spirits of chloroform. The mask may be worn almost continuously or at intervals during the day. The creosote vapour bath is, however, the most satisfactory form of inhalation treatment, and is of great value. This should be given in a concrete-floored room without furniture. The patient is covered with a smock, the eyes are protected by closely-fitting goggles, and the nostrils by cotton wool plugs. A small quantity of creosote is heated in a metal dish, on a tripod over a spirit lamp. When the patient inhales the vapour, which quickly fills the room, violent cough is excited and the cavity is emptied. The ensuing deep inspirations carry down creosote-laden air into the air passages. The baths should be at first given on alternate days and last from 10 to 15 minutes. When the patient becomes accustomed to them, they may be given daily for half an hour or longer. The results are often strikingly beneficial. Vaccines made from the predominant organisms found in the sputum have been given with benefit in some cases. Surgical treatment is now more often employed than formerly. Repeated washing-out through a bronchoscope, at weekly intervals, is often helpful, giving comfort to the patient by diminishing the amount of sputum, and lessening or abolishing its fetor. Induction of artificial pneumothorax is sometimes of value, especially in early cases, in which it may be successful. Unfortunately it is often impracticable, owing to adhesions, and even in cases in which it is carried out, the beneficial effect only persists as a rule while the collapse is maintained. Temporary or permanent paralysis of the phrenic nerve has also proved helpful, especially in localised basal cases and in those secondary to abscess of the lung. Lebectomy or pneumonectomy is proving a satisfactory and effective method of cure in unilateral cases. The mortality from these operations is rapidly lessening with recent improvements in technique.

INJURY

External trauma applied to the chest-wall may cause rupture of a main bronchus. This is especially liable to occur after severe crushing accidents. One or other of the main bronchi may be completely severed from the trachea. The chief clinical feature presented in such a case is emphysema of the neck and upper portion of the chest-wall. Death usually ensues in 2 to 3 days.

G. E. Beaumont.

DISEASES OF THE LUNGS

HYPERÆMIA AND ŒDEMA

Hyperæmia of the lungs may be either active or passive. In the former there is an increased supply of arterial blood through the pulmonary and bronchial arterioles. In passive hyperæmia there is engorgement of the pulmonary venous radicles and capillaries. With both forms there is frequently œdema, due to the exudation of serous fluid into the lung alveoli. The term "congestion" is sometimes employed as an alternative to hyperæmia, but owing to its erroneous popular use it is best avoided.

(*a*) Active Hyperæmia

Ætiology.—This may occur in association with any acute inflammatory process affecting the bronchi, lungs or pleura. It sometimes results from the inhalation of pulmonary or bronchial irritants, such as poisonous gases or heated air. Severe muscular exertion and exposure to extreme cold are described as causes, but the former at least is doubtful. An important variety is that known as *collateral* or *fluxionary hyperæmia*, which occurs when there is obstruction to the circulation in the whole or part of one lung, from conditions such as a large or rapidly developing pleural effusion, an extensive and spreading pneumonia, or in association with pneumothorax. This may develop in the sound lung, or in the unaffected parts of that diseased. A primary form of acute hyperæmia, the "maladie de Woillez," has been recognised by French authors, but this is generally regarded as a mild or abortive pneumonia.

The clinical manifestations of acute hyperæmia are merged in those of the processes with which it is associated, and therefore do not need separate description.

(*b*) Passive Hyperæmia

Ætiology.—Passive hyperæmia may be produced by (1) conditions impeding the venous return from the lungs; (2) those leading to increased resistance to the passage of blood through the pulmonary capillaries, and (3) failure of the driving power of the right ventricle. The commonest causes of impeded return are left-sided heart lesions causing overfilling of, and increased pressure in, the left auricle. In mitral stenosis it may occur early and sometimes almost acutely, but aortic and myocardial lesions also lead to it, when the left ventricle fails and the mitral valve yields. Direct obstruction of the pulmonary veins sometimes results from external pressure by aneurysm, mediastinal tumour or enlarged bronchial glands, or from obstruction of the lumen by thrombosis. The passage of blood through the pulmonary capillaries may be impeded by emphysema, chronic bronchitis, pulmonary tuberculosis and fibrosis of the lungs. Failure of the right ventricle occurs in the late stages of right-sided heart lesions, with tricuspid regurgitation, and as a late sequel of left-sided failure.

Passive hyperæmia is obviously in the main dependent on mechanical

factors; it is not surprising, therefore, that gravity seems to play a part in the localisation of its effects, which are usually most marked in the bases or most dependent parts of the lungs. In bedridden, enfeebled or old patients, particularly if myocardial weakness or degeneration coexists, this factor becomes of great importance. Not infrequently some degree of œdema of the bases develops, and the condition is then called hypostatic congestion. If such an area becomes infected the resulting process is known as hypostatic pneumonia. Basal hyperæmia and œdema of the hypostatic type also result from toxæmia due to diseases such as enteric fever, from poisoning by drugs such as morphine, and as a terminal event in many cerebral lesions causing increased intracranial pressure.

Pathology.—The pulmonary veins and capillaries are engorged, with the result that the lung is darker in colour and heavier, while the alveolar walls and septa are swollen. If the condition persists for some time, pigment derived from the hæmoglobin of red corpuscles escaping by diapedesis is deposited in the epithelium of the alveoli and in the fibroblasts in the interalveolar septa. In long-standing cases the lung is firmer than normal and brownish-red in colour, a condition described as *brown induration*. If any degree of œdema is present, serous fluid is found in the alveoli on post-mortem examination, and on section of the lung frothy serous fluid exudes, which may contain some of the pigmented alveolar cells, constituting what are called "cardiac cells." Although congested and œdematous lung is heavier than normal, it usually floats in water.

Symptoms.—In slight degrees of hyperæmia these may be absent or negligible. In more advanced cases, they are those resulting from the impeded circulation through the lungs and the deficient aeration which this entails. Dyspnœa is the most prominent symptom, and it is generally a measure of the degree of hyperæmia. It is markedly increased by exertion of any kind, and in extreme degrees it is distressing and eventually alarming. It may be inspiratory or expiratory in type, and in the latter case it is sometimes described as cardiac asthma. In severe cases there is usually orthopnœa. Cough is almost invariably present, and there is usually some expectoration of frothy fluid, which may be blood-stained. The pigmented cells referred to above as "cardiac cells" may be found in it. Cyanosis is common and indicates the degree of anoxæmia. This may be associated with distension of the jugular veins, and there is often obvious distress. As in other forms of cyanosis there is usually some increase in the number of red corpuscles. The vocal fremitus at the bases may be diminished, the percussion note impaired, the breath-sounds weak and accompanied by rhonchi, crepitations or bubbling râles, although these signs are for the most part due to the associated œdema. In addition, the signs of the primary condition in the lungs or heart will be apparent.

Complications.—Pulmonary œdema and infarction are the chief complications.

Course.—If the venous engorgement cannot be removed, it usually tends to become progressively worse, whereas when it results from temporary cardiac embarrassment, recovery is usually complete as soon as the heart function is restored.

Prognosis.—This condition has to be distinguished from (1) chronic bronchitis, in which case there may be some rise of temperature and the

physical signs are more variable and more disseminated; (2) infarction, in which pain and hæmoptysis of sudden onset are the rule.

Prognosis.—This is so entirely dependent upon the nature and degree of the condition responsible for the engorgement that no general rule can be formulated.

Treatment.—In elderly patients, or those likely to be confined to bed for long periods, attention should be directed to the decubitus. This should be changed frequently, and if possible the patient should be permitted to sit up or to get into a chair, and encouraged to take a few deep breaths several times during the day. If the hyperæmia is associated with cyanosis and engorgement of the right heart, bleeding to the extent of 8 to 12 ounces may be helpful. If this is not practicable, the application of 6 leeches over the liver, or dry cupping of the bases of the lungs may be tried. Free purgation and the administration of diuretics, notably injection of mersalyl (salyrgan) or neptal may also help indirectly to relieve the engorgement. In cases associated with cardiac failure, the administration of cardiac tonics, such as digitalis, strophanthus or squills, the injection of strychnine, camphor in oil or niketha mide (coramine) may all be of assistance. Moderate hæmoptysis should not be checked, and cough, if effective, may be promoted by suitable expectorants. In cardiac cases a "régime lactée" or strict milk diet is advocated by some French physicians.

(c) Acute or Hyperacute Pulmonary Œdema

In this condition flooding of the alveoli with the serous exudate from the pulmonary capillaries occurs with great rapidity.

Ætiology.—It is more commonly met with after the age of 40 than before, although cases have been recorded in children. It is considerably more frequent in the female than in the male sex. Arterial disease and hypertension are the most common antecedents, but acute or chronic renal disease and pregnancy may all act as predisposing factors. It sometimes occurs in diabetes. The actual exciting cause is often obscure, and probably varies in different cases. A heavy meal, an epileptic fit, or the administration of an anæsthetic may be the immediate cause in those predisposed. In other cases it may be a manifestation of angio-neurotic œdema. Sometimes paracentesis of a pleural effusion is quickly followed by œdema, no doubt as a result of a collateral hyperæmia. It has occurred after "gassing" by chlorine. In diabetes the lipæmic condition which sometimes occurs has been suggested as the determining factor, possibly causing multiple fat embolism. Coronary occlusion and acute left ventricular failure are noteworthy causes. In some cases dissociation of the action of the two ventricles has been supposed to be the cause, the right contracting forcibly while the left is in an enfeebled or asystolic condition. In support of this contention may be adduced the fact that acute pulmonary œdema has been observed after rupture of the chordæ tendineæ of the mitral valve.

Pathology.—The alveoli are found to be flooded with a thin serous exudate. The lungs are heavier than normal, sodden, and on squeezing exude large quantities of greyish-yellow or pinkish fluid. Frothy fluid of similar character is found in the bronchi and even in the trachea and naso-pharynx in hyperacute cases.

Symptoms.—The onset is sudden, and generally occurs when the patient is lying down, hence being most frequently observed at night. The patient awakes with intense dyspnœa, and a sense of suffocation, then frequently rolls or rushes about in the endeavour to breathe, even clutching at the throat. Cyanosis is present, and the aspect is one of anxiety and alarm. Frothy fluid, often pink in colour, may soon stream from mouth and nose, or be brought up in great gulps. The chest movements are hurried, and the accessory respiratory muscles are in violent action. Vocal fremitus is diminished over the lower lobes. The percussion note soon becomes impaired over the lungs, commencing at the bases. The breath-sounds are at first vesicular or harsh with prolonged expiration, then become faint and may be obscured by bubbling râles or crepitations, audible all over the chest. Voice conduction is diminished.

Complications and Sequelæ.—Owing to its acute and rapid course, complications do not occur. Bronchitis may result as a sequela.

Course.—The malady usually lasts only minutes or hours. Unless it remits, or treatment affords relief, the patient rapidly becomes unconscious and death follows, the heart continuing to beat after respirations have ceased.

Diagnosis.—The affection is usually so characteristic that the diagnosis is obvious. In the more protracted cases the dyspnœa and the physical signs are not unlike those of acute suppurative bronchitis or suffocative catarrh and broncho-pneumonia; but in both of these there is some degree of fever and the expectoration is less copious, and when it occurs is usually of purulent or muco-purulent character. The nocturnal onset of œdema may suggest asthma; but the physical signs and the late and scanty expectoration in the latter suffice to distinguish it.

Prognosis.—The prognosis is always very grave; but prompt treatment has saved some cases. Death may occur in less than 10 minutes, or be delayed for 24 or 48 hours. In the angio-neurotic type repeated attacks may occur.

Treatment.—The most successful treatment is the immediate subcutaneous injection of gr. $\frac{1}{4}$ morphine. Good results have also followed the injection of gr. $\frac{1}{100}$–$\frac{1}{50}$ atropine sulphate hypodermically. These are often given together. Oxygen inhalation by nasal catheter or special mask such as the B.L.B. variety may be used. Prompt venesection has been recommended, and should be tried if possible.

(*d*) Chronic Pulmonary Œdema

This is usually the sequel of chronic passive hyperæmia, and the causes and symptoms are those of that condition. It may also occur in chronic renal disease. In marked degrees of œdema, however, the signs may closely simulate those of pleural effusion, save for the displacement of the cardiac impulse. It is important to remember that some degree of hydrothorax may occur as a complication, and increase the difficulty in diagnosis.

INFARCTION OF THE LUNGS

Infarction of the lungs or "pulmonary apoplexy" results when a branch of the pulmonary artery becomes occluded by embolism or thrombosis.

Ætiology.—*Embolic forms.*—The obstructing plug may originate in any part of the systemic venous system, in the right side of the heart or on its valves or in the pulmonary artery itself. The commonest peripheral cause of embolism is detachment of a thrombus in cases of thrombo-phlebitis. This may occur in the veins of the lower extremity, or in those of the uterus after childbirth. Thrombosis with embolic detachment may also develop in prolonged or wasting diseases, such as enteric fever, tuberculosis and cancer; in acute processes, such as influenza, septicæmia and pyæmia; and in localised septic lesions, such as otitis. Pulmonary embolism is not infrequently observed after abdominal or pelvic operations, and after the radical cure of hernia or hæmorrhoids.

Intracardiac thrombi from the right auricle or ventricle, becoming detached, lead to embolism, and this occurs especially in cases of right-sided heart failure secondary to left-sided valve lesions. Vegetations forming on the tricuspid or pulmonary valves in septic endocarditis on detachment produce pulmonary infarction. Rarer causes are fat embolism after injury to bone or to a fatty liver, the entry of pieces of new-growth or hydatid daughter-cysts into systemic veins, and even air embolism.

The exciting cause of embolism is not infrequently sudden movement or strain leading to detachment of a thrombus or vegetations.

Thrombotic forms.—Thrombosis occurs as a secondary process around pulmonary emboli; but it is probable that some cases of infarction are due to a primary thrombosis. This condition may be produced by some acute or chronic pulmonary disease, such as gangrene, tuberculosis and fibrosis, and by atheroma of the pulmonary artery. Any process leading to chronic venous hyperæmia may also cause it. A rare cause is thrombo-phlebitis migrans.

Pathology.—Although the pulmonary arteries are not strictly speaking end arteries, since there is some degree of anastomosis between them and the bronchial arterioles, yet the result of their obstruction is to produce infarcts comparable with those in other organs. The origin of the blood in the obstructed area has been much discussed. Cohnheim regarded it as the result of regurgitation from the veins, a view subsequently disproved, since the infarct is hæmorrhagic even when the veins are also obstructed. It is now regarded as due to influx from the anastomosing bronchial capillaries into the pulmonary capillaries, and the escape of this blood from the latter owing to their altered nutrition. It is generally accepted that embolism is much more common than thrombosis. It has been suggested that some infarcts are not obstructive, but are the result of hæmorrhage *per rhexin* in cases of extreme passive hyperæmia, and that the shape is due to the alveolar distribution of the bronchial area affected. If a large embolus has caused sudden death, it will be found arrested at the bifurcation of a large branch of the pulmonary artery, or even in one of the main divisions of that vessel. In such cases there has not been time for pulmonary changes to occur, and the chief post-mortem condition found is engorgement of the right side of the heart.

In post-mortem examination of cases where smaller emboli have led to infarction, the infarcts are usually found in the lower lobes, more commonly in the right lung. They extend to the surface in the majority of cases, and can be seen before section as slightly raised, dark red areas, with the over-

lying pleura a little roughened from inflammatory exudate. They feel hard and firm, and on section are typically wedge-shaped, with the base on the surface and the apex centrally placed. In the rare deep-seated infarcts a spheroidal form is the rule. When recent, an infarct is dark red in colour, and suggests hæmorrhage with clot formation, hence the term "pulmonary apoplexy." In some cases infarcts have a purplish hue, and are said to resemble the colour of damson cheese; later they change to brownish-red. Infarcted areas sink in water. There may be a single large infarct almost occupying one lobe, sometimes only a small one, or several of varying size and age scattered throughout the lungs. In some cases a fortunate section may reveal the embolus with its ensheathing thrombus, but sometimes a thrombus only is found. Microscopically, the alveoli and finer bronchioles are filled with red blood corpuscles, and there is a sharp delimitation from the healthy lung. If the embolus is infective, suppuration occurs, and abscess or empyema ensues.

Symptoms.—If a large embolus blocks one of the main divisions of the pulmonary artery, there is sudden intense dyspnœa, pain in the chest, distress, cyanosis, and rapid unconsciousness, death resulting in a few minutes from asphyxia. In other cases the patient gives a short cry, and falls unconscious, death occurring almost immediately from syncope. In some cases unconsciousness develops so rapidly, and the respiratory symptoms are so little apparent, that a cerebral vascular lesion may be suspected. On the other hand, life may be maintained for several minutes or even hours, the patient being unconscious or in acute distress and anxiety with urgent dyspnœa, lividity and cyanosis. Respiration is deep and laboured, but fails to give relief to the sense of suffocation. In such cases also, death may result eventually from asphyxia or syncope, or the patient may slowly recover. In less severe forms, such as occur in cardiac and in some post-operative cases, there is sudden pain with difficulty in breathing, followed in a few hours or in a day or two by cough with hæmoptysis or by the expectoration of deeply blood-stained mucus persisting for some days, and slowly clearing up. If the embolus is infective, fever, often of hectic type, results, sometimes delayed for a day or more.

In the severe cases there is cyanosis, distension of the veins of the neck, acute anxiety with exophthalmos and cold, clammy skin. The only physical signs apparent are the deep, laboured breathing, the harsh breath-sounds, and the evidence of cardiac embarrassment with feeble, failing pulse.

In less severe cases the signs are also not characteristic. There are evidences of cyanosis and distress of less urgent character, possibly some limitation of movement on the affected side, increase of vocal fremitus, localised dullness, with weak or absent breath-sounds, and sometimes a pleural rub. In some cases definite bronchial or tubular breath-sounds may be audible. A few fine râles are sometimes present in the adjacent lung areas.

Complications and Sequelæ.—Localised dry pleurisy is almost invariably present. With infective emboli, abscess or gangrene, and later empyema may result. In organisation an infarct leads to a localised area of fibrosis.

Course.—As already described, death may occur from asphyxia or syncope in the course of a few minutes or hours, although recovery occurs in some very severe cases. In the less severe forms, after the initial urgent symptoms

have passed off, recovery is often rapid and uneventful, save for pain, cough and bloodstained expectoration.

Diagnosis.—The dramatic onset, the history and the associated lesions of the veins or heart render diagnosis easy as a rule; but it may be necessary to eliminate other causes of hæmoptysis, notably pulmonary tuberculosis and chronic venous hyperæmia.

Prognosis.—This depends largely upon the initial shock. The prognosis is very grave when the patient rapidly becomes unconscious. As there is less likelihood of sepsis in cases due to cardiac lesions than in those due to localised venous thrombosis, the prognosis is rather better in the former; but, on the other hand, organisation of a clot in a vein may completely remove the source of the emboli, while the source often persists when they are derived from the heart.

Treatment.—The coagulability of the blood may be lowered by the administration of 30 grains of sodium citrate three times daily. This is a wise prophylactic measure in prolonged illness, especially when a milk régime is being enforced. When thrombosis has occurred in a peripheral vein, such as in the leg, the affected limb should be immobilised until organisation of the clot has taken place. Morphine is useful in quieting a patient if there is much mental distress when a pulmonary infarct forms; but usually the patient is collapsed and stimulant measures are indicated. An injection of morphine gr. $\frac{1}{6}$, atropine gr. $\frac{1}{100}$, and strychnine gr. $\frac{1}{30}$ is found of value in some cases. If there is dyspnœa oxygen should be administered. Venesection to the extent of 10 or 12 ounces may be tried in cases where there is marked lividity with a forcibly acting heart. Hæmoptysis, when it occurs, should not be checked. Pain may be relieved by leeches, cupping or by application of iodine. In cases with heart failure the appropriate treatment by cardiac tonics should be administered. A few cases are on record in which immediate surgical aid has been available and the operation of embolectomy has been successful.

COLLAPSE OF THE LUNGS

In collapse of the lungs the alveoli are completely or partly devoid of air. The condition may be congenital, and due to non-expansion of the lung, when it is referred to as atelectasis. On the other hand, collapse may be the result of removal of the air from lung tissue previously expanded, when it is called apneumatosis or acquired collapse. The three terms—collapse, atelectasis and apneumatosis—are, however, used as synonyms by many writers.

Atelectasis or Congenital Collapse

Ætiology.—This condition occurs in still-born and in premature infants, and probably persists to some degree for weeks or even months in weakly children. It may result from immaturity or from weakness of the inspiratory muscles, and from obstruction of the air passages by mucus and meconium. It may be a consequence of disease, such as congenital syphilis or lesions and developmental defects of the nervous system.

Pathology.—Atelectasis is due to failure of the respiratory mechanism

to draw air into the alveoli and expand them, as occurs normally with the first few inspiratory efforts of the newborn infant.

Atelectatic lungs are solid, airless and small. They are usually described as presenting appearances similar to those of adult liver as regards colour and consistence. In partial atelectasis the lung appears mottled, and small expanded areas of pinkish colour may project from the surface. The condition is chiefly of medico-legal and pathological interest.

Apneumatosis or Acquired Collapse

Collapse of previously expanded lung may be active or passive, the former being due to active shrinking of the lung owing to defects in the inspiratory musculature, the latter to conditions disturbing the pressure relations within the thorax.

1. Active Pulmonary Collapse.

Synonyms.—Active Lobar Collapse; Massive Collapse.

Ætiology.—This condition was first described by William Pasteur in 1890 in cases of diphtheria associated with paralysis of the diaphragm. In 1908 he pointed out that it occurred also as a sequel of operations, especially of those upon the abdominal organs, less frequently of those upon the neck and pelvis. It is highly probable that many post-operative lung conditions formerly recorded as pneumonia were in reality due to active collapse. It may also follow after injuries, such as those resulting from falls from a bicycle or a horse. During the War of 1914–1918, when chest wounds were collected in special hospitals, it was found that massive collapse was not infrequently an important complication of penetrating and non-penetrating wounds of the chest. It was also noticed in some cases after severe wounds of the buttocks and pelvis.

Pathology.—The mechanism by which deflation results is obscure, and is the subject of controversy. Pasteur regarded the condition in the diphtheritic cases as due to paralysis of the diaphragm through the phrenic nerves or their nuclei, and in the post-operative and traumatic cases as a consequence of reflex inhibition of this muscle. Briscoe, on experimental, pathological and clinical evidence discards Pasteur's explanation. He maintains that the deflation is caused by an exaggeration of the normal phenomena of breathing in the supine position, in which he states that the crural portion of the diaphragm alone contracts, the costal portion being in abeyance. In the supine position, with quiet breathing, deflation of the lower lobes occurs, and this is promoted by conditions of debility, toxæmia or operation. The clinical manifestations described by Pasteur are regarded by Briscoe as the result of superadded pleurisy, or of inflammation of the crura of the diaphragm.

Boland and Sheret have put forward the suggestion that massive collapse is due to obstruction of the bronchi, followed by removal of the air in the corresponding lung areas by absorption into the blood stream. The obstruction is supposed to be due to increased secretion and the inhibition of the cough reflex.

Post mortem, the lower lobe of one lung is usually found to be deflated and retracted towards the spine. Sometimes the whole of one lung may be affected, or both lower lobes. The collapsed area is bluish-red, firm, does not crepitate and sinks in water. Pleurisy or pneumonic changes may be

seen, and these are regarded by Pasteur as secondary to infection of the deflated lung, the resistance of which is lowered, and by Briscoe as the essential factor in the production of the symptoms. In massive collapse the heart and mediastinum are displaced towards the affected side, and the sound lung is often bulky and distended.

Symptoms.—The symptoms commonly commence within 24 or 48 hours of the injury or operation, although they may rarely be delayed for 5 to 7 days. The onset is generally sudden, with pain in the lower part of the thorax or behind the sternum. Severe dyspnœa quickly follows, and the patient appears dusky, cyanosed and alarmingly ill. Cough, with viscid mucoid expectoration, generally develops in a few hours. The latter may become copious and muco-purulent if pneumonic changes ensue. The pulse and respirations are markedly increased in rate, and the temperature not infrequently rises to 103° F. Occasionally the onset is more gradual with pain and cough, and in some cases of wounds it may give rise to few symptoms and be discovered only on routine examination.

Examination of the chest shows diminished movement on the affected side, and often absence or reversal of epigastric excursion with respiration, whereas the movement on the other side may be exaggerated. In other respects the signs usually simulate those of lobar pneumonia. Over the collapsed lung the vocal fremitus is increased, the percussion note is dull, the breath-sounds are tubular, and bronchophony and whispering pectoriloquy are present; but as a rule there are no adventitious sounds, although occasionally rhonchi and a few fine râles may be heard. In some cases the breath sounds are very weak or almost absent, and voice conduction is diminished. Over the healthy lung, loud and harsh breathing is audible. The displacement of the cardiac impulse towards the collapsed lung is a point of cardinal importance. It is noteworthy that in certain cases of gunshot wounds of the chest the collapse affects the contra-lateral lung.

Complications and Sequelæ.—Bronchitis, lobar pneumonia, or pleurisy may occur as complications. There are usually no sequelæ, except that pleural adhesions may occur.

Course.—The course of the affection is rapid. After periods extending from 2 to 5 days the temperature falls to normal, the symptoms disappear, the lung quickly re-expands, the heart returns to its normal position, and there is complete recovery.

Diagnosis.—The most important conditions from which this malady has to be distinguished are lobar pneumonia, pulmonary embolism, pneumothorax and pleural effusion. The position of the cardiac impulse is often the deciding factor: in collapse it is displaced towards the lung involved, in pleural effusion and pneumothorax it moves away from the affected side, whereas in lobar pneumonia there is usually no cardiac displacement, although there may be dilatation. Labial herpes and blood-stained expectoration are frequently seen in pneumonia, but not in collapse. When in right-sided collapse there is marked distension of the left lung with obliteration of the normal cardiac dullness, the signs superficially resemble those of a left-sided pneumothorax; but with careful examination no such error should be made. The distinction from pulmonary embolism may be difficult at first, but the localisation of the signs, and the blood-stained expectoration, may give useful indications.

Treatment.—PROPHYLACTIC.—The administration of morphine and atropine before the anæsthetic, propping up of the patient in bed as soon as possible after it, and the insistence upon periodic deep breaths are useful measures in preventing the onset of lobar collapse. When the "collapse attack" develops oxygen should be administered and pain relieved by local applications, such as leeches or poultices, or by an injection of morphine, atropine and strychnine. Expectorants may be given if the cough is ineffective, and cardiac tonics, such as digitalis, strophanthus and caffeine if there is much cardiac embarrassment. Injections of strychnine or coramine are useful if the patient is collapsed at the onset. Bronchoscopic aspiration has been recommended in cases of post-operative massive collapse.

2. PASSIVE PULMONARY COLLAPSE.

This form of collapse may affect the whole of one lung, or be confined to one lobe or to groups of lobules.

Ætiology.—Total collapse is generally the result of pleural effusion, empyema, pneumothorax or obstruction of a main bronchus. In a large effusion and in pneumothorax collapse is complete, unless the shrinkage is prevented by adhesions. In a smaller effusion, the process may be limited to the lower parts of the lung. Other causes of lobar or partial lobar collapse are conditions leading to complete obstruction of a main bronchial division, particularly new-growth, aneurysm or foreign body. It also occurs in aged or bedridden patients, or in those with enfeebled inspiratory muscles, when prolonged fever has enforced a dorsal decubitus. Abdominal distension from tympanites or ascites can also cause collapse of the bases of the lungs.

Lobular collapse results from any condition impeding the air entry to the smaller bronchi or bronchioles, such as bronchitis, broncho-pneumonia, pulmonary tuberculosis, whooping-cough and diphtheria. Obstruction of the naso-pharynx by enlarged tonsils and adenoids may cause partial collapse, especially in the upper lobes.

Pathology.—The deflation of the lung area may be produced in three ways—(1) By complete obstruction to the air from blocking of a bronchus or bronchiole, the residual air being absorbed; (2) by enfeeblement of the inspiratory mechanism similar to the process in active collapse; and (3) by disturbance of the intrapleural pressure by fluid or air, the lung at first contracting in virtue of its elasticity until the intrapleural pressure becomes equal to that of the atmosphere, when any further accumulation of fluid or air causes positive pressure and compression of the collapsed lung.

Post mortem, in complete or lobar collapse the appearances are similar to those in active collapse. In lobular collapse the deflated areas are contracted and depressed below the level of the healthy lung. They are dark red or slaty in colour, while the adjacent areas are pinkish and often emphysematous. The collapsed areas do not crepitate.

Symptoms.—Total collapse of the lung or of a lobe being usually a secondary process, the symptoms and signs are masked by those of the primary condition, such as pleural effusion, pneumothorax, growth or aneurysm. It can, however, usually be demonstrated by X-ray examination, the collapsed lung being apparent as a fairly dense shadow lying alongside the vertebral bodies. Not infrequently, however, in pleural effusion definite tubular breath sounds, with bronchophony and pectoriloquy, may

be audible in the relatively dull area above the level of the fluid posteriorly, and these signs are due to the collapsed lung. In aortic aneurysm, or less commonly in mediastinal, pulmonary and bronchial neoplasms, distinctive signs due to the local collapse may be apparent. These consist of slightly diminished movement of the corresponding part of the chest wall, with diminution of vocal fremitus and impairment of percussion note or actual dullness. Breath-sounds are weak, as a rule, but may be bronchial or tubular. Voice conduction is increased, and in incomplete collapse crepitations are often audible. The cardiac impulse may be displaced towards the affected side, but this is less apparent than in active collapse, and it is not infrequently displaced to the opposite side by the primary condition. Lobular collapse gives rise to no symptoms which can be differentiated from those of the condition inducing it.

Complications and Course.—The lung usually re-expands wholly or in part when the condition causing collapse has been removed. Thus a lung that has been maintained continuously collapsed by artificial pneumothorax, with repeated refills for as long as 4 years or more, will re-expand when the gas in the pleural cavity is not replaced. In chronic effusion, or in large or neglected empyemata, re-expansion may be incomplete, and some falling in of the chest wall results. Fibroid changes may occur in lung tissue which has been long collapsed.

Diagnosis.—This is frequently a matter of inference, owing to the nature of the primary disease. Valuable help may be afforded by X-ray examination.

Treatment.—No special treatment apart from that of the condition causing the collapse is required. If a pleural effusion is slow to absorb, the necessity for paracentesis or gas replacement, to avoid pleural thickening, may have to be considered.

HÆMOPTYSIS

It should be recognised that hæmoptysis is a symptom, not a disease. It is here considered separately because the accurate diagnosis of its origin is essential to its treatment, which differs widely in different conditions.

Definition.—The term hæmoptysis is arbitrarily restricted to the expectoration of blood, entering the air passages from structures below the larynx or from the larynx itself. When the blood is derived from the naso-pharynx or mouth it is sometimes described as spurious hæmoptysis.

Ætiology.—1. **Pulmonary tuberculosis** is the commonest cause, the blood being derived from an aneurysm in a pulmonary cavity, or from ulceration of a small vessel, or congestive processes around the early lesions.

2. **Chronic venous congestion**, particularly in mitral stenosis. These two conditions account for the majority of cases.

3. **Inflammatory and destructive diseases of the lungs, air passages or pleura**, such as pneumonia, broncho-pneumonia, especially the influenzal variety, abscess, gangrene and bronchiectasis with ulceration of the walls. A latent bronchiectasis without sputum may cause recurrent hæmoptysis (*forme hémoptoïque sèche*). Pneumokoniosis, streptotrichosis and ulceration of the larynx, trachea or bronchi from tuberculosis, gumma or new-growth

may also be associated with hæmoptysis. Breaking down of a caseous or calcareous bronchial gland is a rare cause, as also is rupture of an empyema through a bronchus.

4. Infarction of the lung from embolic or thrombotic obstruction.

5. New-growths of the lung, bronchi or mediastinal glands.

6. An aortic aneurysm may cause hæmoptysis by "weeping" through an eroded bronchus, or by direct rupture, the latter being of course immediately fatal.

7. Traumatic causes.—Injury may cause hæmoptysis, by fractured ribs wounding the lung, by contusion and by breaking down of healed tuberculous lesions. Hæmoptysis occurs frequently in wounds of the chest, both penetrating and non-penetrating. A foreign body, such as a piece of shrapnel, may lie dormant for years, and then cause recurrent hæmoptysis.

8. Certain abnormal blood conditions, chiefly leukæmia, purpura, hæmophilia, scurvy, minor degrees of vitamin C deficiency and occasionally pernicious anæmia. Hæmoptysis occasionally occurs in the malignant specific fevers, especially small-pox and measles.

9. Parasitic causes, such as pulmonary distomatosis and spirochætosis, are common in Asia but rare in Europe. Hydatid disease of the lung may cause repeated slight hæmorrhages.

10. Vicarious menstruation.—Some cases in women have been regarded as vicarious menstruation, and this view dates back to Hippocrates. It is probable, however, that most cases are to be explained as due to leakage from obscure pulmonary lesions.

11. Hæmoptysis occasionally occurs in apparently healthy persons. In some, with high systemic arterial tension, it is probable that the pulmonary arterial pressure is also raised, and the condition may be regarded as analogous to the epistaxis which occurs more commonly in such patients. Sometimes the hæmoptysis is due to leaking from an old arrested tuberculous lesion.

12. Rupture of an hepatic abscess or hydatid cyst through the diaphragm into a bronchus is an occasional cause.

Spurious hæmoptysis is usually due to staining of the saliva or the pharyngeal secretion with blood, generally derived from the gums, which are spongy and congested, often from early pyorrhœa. The condition is common in anæmic girls, and is, as a rule, observed in the morning. Hæmorrhage from an enlarged pharyngeal vein is often suggested as a cause, but is rarely seen. Hæmorrhage after tooth extraction, and staining of the mucus expectorated after epistaxis, are other causes of spurious hæmoptysis.

Pathology.—From the list of causes it might be inferred that the origin of the blood differs in different cases. It may come from the pulmonary or bronchial vessels in pulmonary tuberculosis and other lung or bronchial conditions, and also in chronic venous congestion or infarction. It may come from the thoracic aorta direct, or from some of its branches, in aneurysm and mediastinal new-growth, and from the hepatic vessels in abscess of the liver. In cases due to disease of the trachea and larynx it comes direct from the vessels supplying them.

Post mortem, the larynx, trachea and bronchi may contain clots, or blood-stained froth and mucus, and their walls may be stained in places. Dark reddish areas of lobular distribution, due to inhaled blood, may be seen

in various parts of the lungs, particularly at the bases. Sometimes this may induce bronchitic changes, described as hæmoptoic bronchitis. Careful search in cases of profuse hæmoptysis will usually reveal the source of the hæmorrhage, and in pulmonary tuberculosis this is generally a ruptured aneurysmal dilatation in a cavity or an ulcerated vessel. The aneurysm may be small and escape notice unless many cuts are made into the lung.

Symptoms.—In hæmoptysis, the patient often experiences a tickling in the throat, followed by a gush into the mouth with a salt taste, and on expectoration notices blood. The alarm and anxiety this occasions lead to restlessness and rapid action of the heart. If the bleeding is profuse, cough is frequent, and large clots, together with liquid alkaline blood, may be expectorated to the extent of 20 or 30 ounces in a few hours. The bleeding may cease temporarily, to recur at intervals for several days, until the patient becomes blanched, weak and syncopal, with rapid, weak pulse. In any profuse hæmoptysis, death may occur in a few minutes, either from asphyxia or syncope. In the former case, the blood, at first bright and arterial, is soon dark and frothed, while the patient becomes cyanosed and livid. In slighter degrees of hæmoptysis there may be only streaks, small clots or liquid blood mixed with ordinary sputum. After the actual bleeding has ceased, the sputum may be blood-stained for some days, owing to the expectoration of blood inhaled into other parts of the lungs. This can be recognised by its colour, which varies from dark red to brown, owing to the changes undergone by the blood pigment.

Diagnosis.—This involves two problems—first the differentiation from hæmatemesis and spurious hæmoptysis, and secondly the recognition of the cause of the hæmorrhage. If the patient is seen at the time of the bleeding the first of these is easy. The nature of the blood, and its association with cough and possibly with pulmonary or cardiac signs, are conclusive. When the diagnosis has to be made upon the history given by the patient or by friends it may be difficult, especially in the absence of physical signs.

In hæmatemesis there is frequently gastric pain and faintness before the vomiting, the blood is acid in reaction, dark in colour, even brown from acid hæmatin, and is sometimes mixed with food. The fact that in hæmoptysis blood may be swallowed and subsequently vomited increases the difficulty. Patients often give very dubious answers to questions as to whether the blood was coughed or vomited up. They should then be questioned as to whether sputum was brought up on the following day, and, if so, whether it was blood-stained. In cases of doubt the investigation of the pulmonary and abdominal physical signs, when the patient's condition permits, may decide the diagnosis.

The utmost caution should be exercised to exclude tuberculosis before making a diagnosis of "spurious hæmoptysis." Only when there are no pulmonary symptoms, signs or X-ray indications, and when some obvious cause, such as anæmia or pyorrhœa, is found, is it safe to do so.

While distinguishing between the various causes of hæmoptysis it is well to regard and to treat it as due to pulmonary tuberculosis until some other cause is conclusively established. The sputum should be examined for tubercle bacilli on several occasions, the temperature recorded and the physical signs including X-ray appearances most carefully watched.

The presence of a valvular lesion, especially mitral stenosis with signs of

pulmonary engorgement, may render the cause of hæmoptysis clear. When tuberculosis and cardiac disease can be excluded, a careful study of the history, the symptoms and signs, may throw light on the diagnosis or suggest some investigation which will serve to establish it, *e.g.* examination of the sputum for parasites and hydatid hooklets, the cytological examination of the blood and an X-ray examination.

In other cases, as in bronchiectasis, abscess or gangrene, the history, the physical signs and the nature of the sputum are often characteristic.

In the latent or silent form of bronchiectasis (forme sèche), the condition may be revealed only by lipiodol injection.

Bronchoscopy may be of great value in revealing the presence of adenoma or carcinoma.

Prognosis.—Apart from hæmoptysis, which is rapidly fatal, due to aneurysm or pulmonary tuberculosis, the immediate prognosis in cases of pulmonary hæmorrhage is not unfavourable, even when it continues for days. The ultimate prognosis depends upon the cause.

Treatment.—This is so entirely dependent upon the cause and origin of the bleeding that reference should be made to the corresponding diseases.

EMPHYSEMA OF THE LUNGS

Emphysema of the lungs, or alveolar-ectasis, is a condition of distension of the alveoli; it is usually progressive and is associated with definite changes in the inter-alveolar walls. The following varieties are generally recognised—(1) Large-lunged or hypertrophic; (2) small-lunged or atrophic; (3) compensatory; (4) acute vesicular; and (5) acute interstitial emphysema. The last-named condition has no relation to true emphysema except in name, but will be described in this group for convenience.

1. Large-Lunged or Hypertrophic Emphysema (Substantive or Idiopathic Emphysema)

This is a chronic affection and is usually bilateral.

Ætiology.—*Predisposing causes.*—It may occur at any age, even in childhood, but is most frequently seen in middle and late adult life. It is commoner in men than in women, probably because they are more exposed to the conditions inducing it. Although not strictly hereditary, it often shows a familial incidence. Certain occupations are credited with being concerned in its production, notably those involving violent or prolonged muscular effort with closed or partially closed glottis, such as blowing wind instruments and lifting heavy weights. Dusty occupations also favour its onset by leading to bronchitis and cough.

The common *exciting cause* seems to be the strain of prolonged and repeated cough, induced by chronic bronchitis, bronchiectasis, asthma, whooping-cough, cigarette smoke inhaling, and other causes of irritation of the upper air passages.

Pathology.—The pathogenesis of emphysema has been much debated and various explanations have been offered. (1) **Primary degeneration theory.** Villemin suggested that the essential lesion was a fatty degenera-

tion of the alveolar walls, while Cohnheim believed that there was a congenital defect of the elastic tissue of the lung. (2) The inspiratory theory, first suggested by Laennec and developed by Gairdner, postulates the force of inspiration as the distending agent. (3) The expiratory theory, first enunciated by Mendelssohn, was independently brought forward and established by Jenner. The distension of the alveoli is regarded as due to the effect of forced expiration and cough. Jenner pointed out the special and early involvement of the apices, the anterior and lower margins of the lungs; in other words, the parts least supported by the thoracic cage. (4) Freund regarded the changes in the lungs as secondary to calcification of the costal cartilages, the chest becoming fixed in the inspiratory position and the lung permanently expanded in consequence. The expiratory explanation is now generally accepted, and emphysema is regarded as the result of increased intra-alveolar tension, due to violent expiratory efforts, acting on walls weakened by congenital defects, by inflammatory processes or by toxic agents, such as alcohol (Nothnagel).

The characteristic conformation of the chest is usually apparent (see Symptoms), the costal cartilages are often calcified, and on opening the thorax post mortem, the lungs bulge instead of retracting, so that the pericardium may be almost completely obscured. They are pale in colour, even in town-dwellers, a condition called albinism of the lung by Virchow. They are soft and pit on pressure, and, as described by Laennec, give the sensation of a down pillow. The surface of the lung under the pleura shows a finely vesicular appearance, due to the distension of the alveoli, the vesicles often being nearly as large as pins' heads. Not infrequently large bullæ or blister-like protuberances, varying in size from a pea to a Spanish olive, occasionally much larger, may be seen projecting from the surface, particularly at the apices and margins. These bullæ when incised show fine fibrous bands crossing them, the remains of inter-alveolar walls and of atrophied blood vessels. It was formerly customary to refer to such cases as bullous or marginal emphysema and to describe those in which the dilatation is less obvious but more widely diffused as general emphysema; but the conditions are so commonly associated together in varying degrees that little is gained by so doing. On section the lungs are pale and dry, except at the bases, where there is frequently some œdema in advanced cases. The bronchi may show some general dilatation, although less commonly than might be expected from the close similarity of the causal factors of emphysema and bronchiectasis. When bronchitis coexists, muco-pus can be squeezed from the cross-sections of these tubes. As pointed out by Fowler, pleural adhesion is relatively uncommon. The infundibula and alveoli are dilated, and the inter-alveolar walls are thin and atrophic, even disappearing wholly or in part. The distension and coalescenec of adjacent alveoli result in the formation of bullæ. The calibre of the pulmonary capillaries is diminished by stretching of the alveolar walls, and where atrophy of the inter-alveolar septa occurs the capillaries are destroyed. These two processes result in a considerable diminution in the total aerating surface, and cause the dyspnœa and cyanosis characteristic of the disease. Moreover, the normal anastomoses between the terminal bronchial and pulmonary capillaries increase considerably, and some of the blood in the latter may therefore fail to reach the alveoli and so escape aeration. Atrophic changes in the elastic tissue

have been described. In order to maintain the circulation through the diminished capillary area, the right ventricle hypertrophies and the resultant raised blood pressure sometimes induces atheroma of the pulmonary artery. Emphysema being a progressive lesion, and the defective aeration of the blood perhaps interfering with the nutrition of the heart muscle, cardiac failure eventually ensues, causing tricuspid regurgitation, engorgement of the right auricle, and the visceral effects of venous engorgement, such as "nutmeg" liver. Cabot states that true emphysema is often not found post mortem in cases so diagnosed during life, and prefers to designate the clinical entity here described as "the Barrel Chest."

Symptoms.—Dyspnœa of varying degree is the most characteristic symptom. In uncomplicated cases of moderate extent it is only present on exertion, unless bronchitis coexists. In advanced emphysema, dyspnœa is marked and becomes extreme in the bronchitic or "asthmatic" attacks and in foggy weather. Cyanosis is common, and is to some extent a measure of the degree of emphysema. Varying degrees of polycythæmia may be observed. The patient may walk about with a more extreme degree of cyanosis than in any other condition except congenital heart disease. Clubbing of the fingers of moderate degree is common. Cough is usually due to the associated bronchitis, and is worse in the winter and in foggy weather. It is frequent, noisy and often hacking and paroxysmal. Expectoration is also the result of the bronchial catarrh, and varies from a few grey mucoid pellets to copious muco-pus.

The chest is enlarged, particularly in the anteric-posterior diameter, the upper thoracic spine is rounded and kyphotic, the sternum protrudes forward, and the angle of Louis is prominent, the general effect being the so-called barrel-shaped chest. The ribs run forward more horizontally and the intercostal spaces are wider than normal, the chest being as a whole in the inspiratory position. The respiratory movements are much restricted, the patient elevating the rigid thorax with little expansion on taking a deep breath, so that the inspiratory increase at the level of the nipples may be only half to 1 inch, instead of the normal 2½ to 3 for an adult. There is often filling and even bulging of the supra-clavicular hollow, while the neck appears short, the sternomastoids stand out, and the jugular veins are full. A zone of dilated venules, the "emphysematous girdle," is often present along the line of the costal attachment of the diaphragm, but is not pathognomonic. The cardiac impulse is not visible as a rule, and may only be felt with difficulty, but epigastric pulsation is usually apparent. Vocal fremitus is diminished, and the percussion note is hyper-resonant. The superficial cardiac dullness is greatly diminished or even absent, and the lower limit of pulmonary resonance may extend to the costal margin, back and front, the hepatic dullness being encroached on or obliterated.

It is said that in bullous emphysema the breath-sounds are harsh over the outer part of the upper lobes in front, and weak at the bases. In general emphysema the breath-sounds are weak everywhere, inspiration is short, and expiration is greatly prolonged. A loud rumbling, from contraction of the thoracic muscles, may entirely obscure the breath-sounds. A few fine bubbling râles may be heard at the bases or at the sternal margins. If bronchitis is present, scattered rhonchi may be audible. Vocal resonance is generally slightly diminished. The heart-sounds are weak and distant,

and in late stages a tricuspid systolic murmur may develop. The "vital capacity" of the lungs, measured by a spirometer, is often reduced to one-half or less. Examination by the X-rays shows increased extent, and undue transradiancy of the lung tissue. They show the diaphragm lower in position and flattened, and the costophrenic angle widened. The liver is sometimes palpable, possibly from downward displacement by the bulky lung, but more often from enlargement due to passive hyperæmia. The spleen may also be depressed and enlarged.

Complications.—Bronchitis is the commonest, and often constitutes a vicious circle. Asthmatic attacks, so-called "bronchial asthma," are common in later stages; on the other hand, spasmodic asthma may be the cause of the emphysema. Pneumothorax and interstitial emphysema may occur from rupture of the bullæ, although these accidents are surprisingly rare. Pulmonary tuberculosis is an occasional complication of emphysema, which, contrary to popular opinion, is not antagonistic to it, although it may mask and obscure the early stages. Right-sided cardiac failure, with its train of consecutive changes, is a late and often terminal complication.

Course.—Emphysema is progressive, unless the cause is removed or the effects of the disease are mitigated by residence in a warm, dry climate, especially in the winter. Conversely, residence in unsuitable districts, persistence in detrimental employment, and repeated attacks of bronchitis accelerate its course.

Diagnosis.—This is never difficult in advanced cases. The slighter degrees may be more difficult, and the diagnosis is then largely a matter of inference from the association of chronic cough and dyspnœa, with physical signs of hyper-resonance and prolonged expiration.

Confusion may occasionally arise in regard to pneumothorax and pulmonary tuberculosis. Careful record of the symptoms and signs and the investigation of the sputum generally suffice to distinguish these conditions. In doubtful cases the X-rays may assist.

Prognosis.—This depends upon the degree of emphysema and the circumstances of the patient. If progressive, it exerts an increasingly crippling effect, and it certainly shortens life under urban conditions. A "vital capacity" of less than 50 per cent. of the normal is of serious import. The advent of severe bronchitis or of cardiac complications may affect the prognosis gravely.

Treatment.—Emphysema may be arrested but cannot be cured. Attention must be directed to prevention of the causes of chronic cough and increased intra-alveolar tension. In any person with hereditary tendency to emphysema or to winter cough, the questions of occupation and place of residence should be carefully considered. When the disease is established, the patient, if in a position to afford it, should spend the winter in a warm, more equable climate, either abroad or at the south-west coast of England.

Various attempts have been made to increase the respiratory ventilation of the lungs, *e.g.* by compression of the chest during expiration, by expiring into rarefied air, by breathing compressed air or by expiratory breathing exercises. The patient enters a special iron chamber fitted with a window, and the air pressure is raised during the course of half an hour to $1\frac{2}{3}$ atmospheres. He remains at this pressure for an hour, and is then decompressed to normal during the nest half-hour. These baths may be given every other

day and gradually increased in duration and frequency. This treatment is often helpful in cases of emphysema associated with bronchial spasm or with bronchitis. Cases with marked arterial disease or with much rigidity of the chest-wall are unsuitable for this form of treatment.

The diet should be simple and easily digestible, especially in the later stages. If there is spasmodic dyspnœa or asthma, no late meal should be permitted. Cod-liver oil or halibut liver oil in the winter seems to help some patients. Clothing should be warm, but the excess of under-garments, often worn in fear of chill, is harmful.

In other respects treatment is largely symptomatic. In acute bronchitic attacks the measures to be adopted are in no way different from those in bronchitis uncomplicated by emphysema. In the more chronic bronchitis so commonly present in the winter, iodides with alkalis and balsamic expectorants seem beneficial. Terebene (min. 10) in emulsion or in capsule has been recommended. Counter-irritation to the chest by liniments, such as the lin. terebinthinæ aceticum, is often comforting to the patient, when cough is troublesome. When asthma or paroxysmal dyspnœa occurs, antispasmodic drugs and measures similar to those used in spasmodic asthma may be employed. When cardiac failure supervenes, the appropriate treatment must be vigorously applied. If there is marked cyanosis and venous engorgement, oxygen administration, venesection, leeching, purgative and diuretic drugs may be employed, and digitalis and other cardiac tonics administered. American authorities have suggested the use of an abdominal belt to increase the intra-abdominal pressure and raise the diaphragm.

2. Small-Lunged Emphysema (Atrophic or Senile Emphysema)

Ætiology.—This condition occurs in old age and forms part of the general atrophy of the tissues.

Pathology.—The alveolar walls become thinned and disappear, so that adjacent alveoli coalesce. The condition is primarily atrophic, and therefore differs from true emphysema, although the result is to produce a diminished area for aeration. Post mortem the lungs are small and do not bulge or obscure the pericardium. They are often deeply pigmented, and are more spongy than normal, but although bullæ occur they are small. On section the lung tissue is bloodless and friable. The bronchi may be slightly dilated and show catarrhal changes.

Symptoms.—These are slight and are masked by the enfeeblement due to the general atrophy and debility. There is shortness of breath only on exertion, or on exacerbation of the chronic bronchitis which is frequently present. The chest is small, flat and thinly covered, the movements are poor and there is elevation of the chest as a whole, with poor expansion. Kountz and Alexander maintain that there is very little diminution in vital capacity, that the movements of the diaphragm are increased and that the intervertebral discs are abnormal. There is little cyanosis, and no clubbing. The vocal fremitus is unaltered or slightly diminished. The percussion note is hyper-resonant, but there is no encroachment on the cardiac and hepatic areas of dullness. Breath-sounds are weak, and there is but little prolongation of expiration. Rhonchi and râles may be heard, especially if bronchitis is present, or if the heart is failing.

Diagnosis.—The condition is generally so obvious that no difficulty arises.

Treatment.—This is chiefly a matter of careful regimen and diet, with treatment of coexisting bronchitis or cardiac failure.

3. Compensatory Emphysema (Localised or Secondary Emphysema)

Ætiology.—Localised emphysema is a sequel to some process inducing collapse, contraction or destruction of areas of lung tissue. It may be lobular in distribution in bronchitis, broncho-pneumonia, tuberculosis and diphtheria. It may affect one or more lobes, or the whole of one lung, especially in cases of fibrosis following tuberculosis, pneumonia, chronic pleural effusion and empyema.

Pathology.—It is generally conceded that the inspiratory theory of Laennec and Gairdner satisfactorily explains the genesis of this condition. When shrinkage of an area of lung occurs, the chest wall may fall in, if there is pleural adhesion, but otherwise inspiration tends to expand the normal parts of the lungs. None the less, it must be admitted that the expiratory strain of cough may assist in its production.

Although it may be compensatory and physiological at its inception, it is doubtful whether a true hypertrophy takes place after adolescence. In any case it soon leads to atrophy of the alveolar walls, as in true emphysema, and thus becomes pathological and harmful. Post mortem the condition may be found in an upper lobe around contracted scarred lung tissue, or in a lower lobe when the upper lobe is contracted or disorganised. In cases where one lung is fibroid and contracted, compensatory emphysema may be found throughout the sound lung. The resulting adaptations caused by enlargement of one part and shrinking of another may produce some striking displacements, the lower lobe extending upwards nearly to the clavicle, or the anterior margin of the sound lung crossing the mid line. The general appearances are closely similar to those of ordinary emphysema, except that bullæ do not occur, at any rate until the process is advanced and definitely pathological.

Symptoms.—This condition does not produce symptoms that can be differentiated from those of the primary disease. When it affects a lobe or the whole of one lung, there is hyper-resonance over the area involved, which often contrasts strikingly with the dullness due to the primary lesion. The hyper-resonance may extend across the sternum and even for an inch or more beyond it. The heart is displaced towards the side where fibrosis is in progress. Vocal fremitus and vocal resonance are little altered, but may be increased at first and subsequently diminished. In the early stages, when there is alveolar dilatation without degenerative mural changes, the breath-sounds are exaggerated, harsh or puerile, but when such processes develop, they become weak and there are indications of dyspnœa and cyanosis on exertion.

Diagnosis.—This is easy, owing to the difference between the diseased and "compensatory" areas, and to the indications of contraction and displacement.

Treatment.—No special treatment apart from that of the primary condition is required.

4. Acute Vesicular Emphysema

Although custom has included this condition with emphysema, it is in reality only a temporary acute distension of the alveoli resulting from any condition causing widespread obstruction of the smaller bronchi. It is sometimes observed after death in cases of acute bronchitis, whooping-cough or asphyxia and in anaphylactic shock, and its existence may be inferred in severe asthma. Post mortem the lungs are bulky and the alveoli distended.

The symptoms are dependent upon the primary condition, although dyspnœa is invariably present. The chest is found to be fully expanded, the vocal fremitus is diminished, the percussion note is hyper-resonant, and the breath-sounds vary with the condition inducing it.

5. Acute Interstitial Emphysema

In acute interstitial emphysema air is present in the stroma of the lungs, and in the subpleural connective tissues. It may follow external trauma, such as fractured ribs, or wounds penetrating the lungs. The alveoli may rupture with violent expiratory efforts, as occur in whooping-cough or influenzal broncho-pneumonia. It may occur in diphtheria. The air sometimes tracks along the pulmonary roots to the mediastinum, and appearing in the neck or on the chest-wall gives rise to surgical emphysema.

Post mortem, subpleural bullæ may be seen containing air, and on section of the lung minute air bubbles may be found in the inter-alveolar connective tissue. A diagnosis cannot be made unless the physical signs of surgical emphysema are present. The air is usually completely absorbed, and a perfect recovery takes place. No special treatment is required beyond keeping the patient at rest, and giving sedative drugs to allay cough.

ABSCESS OF THE LUNG

Definition.—Abscess of the lung includes any circumscribed collection of pus formed in the lung tissue, but softened tuberculous areas and bronchiectatic accumulations are usually excluded.

Ætiology.—*Predisposing causes.*— These include any diseases producing general cachexia or malnutrition, notably diabetes and chronic alcoholism, also any conditions leading to diminished resistance locally in the lung, such as injury, disease or exposure.

Exciting causes.—These are pyogenic organisms, which reach the lung by inhalation, by extension from adjacent suppurative processes, or by the blood stream, either directly or in septic emboli. The common organisms found are streptococci, staphylococci, the pneumococcus, Friedländer's pneumo-bacillus, *Bacillus welchii* and the *Bacillus coli*—sometimes acting in conjunction with putrefactive bacteria. Spirochætes, *Bacillus fusiformis*, treponemata and anaerobic organisms are often present, especially after rupture has occurred. Pulmonary abscess may form under the following conditions:

(1) After inhalation of foreign material into a bronchus. This may be a foreign body, or may occur in association with septic conditions in the nose,

nasopharynx and larynx, or during and after operations in these regions. These are referred to as inhalation abscesses, though some post-operative cases are regarded as due to embolism and not to inhalation. (2) As a result of lobar or lobular pneumonia, especially after the deglutition and aspiration varieties of the latter. Such abscesses are sometimes called metapneumonic. (3) Embolic causes—in pyæmia, or following on septic pulmonary emboli due to right-sided septic endocarditis, or derived from distant septic processes, such as otitis media, and infective thrombo-phlebitis. Amœbic abscess occurs occasionally after dysentery, and pulmonary abscess may be found as a rare complication of enteric fever. (4) From infection of the lung tissue due to spread from adjacent disease. This may occur in bronchiectasis, in ulcerating new growths of the lung, bronchi, œsophagus or mediastinal glands, in caries of the vertebræ or ribs, and in suppurating mediastinal glands. Rupture of an empyema, of a subphrenic abscess, of a liver abscess, or of infected hydatid cysts of the lung or liver may also lead to pulmonary suppuration. Ten per cent. of cases of abscess are due to new growths. (5) As a sequel of perforating chest wounds, or of fractured ribs piercing the lung.

Pathology.—Abscess of the lung is generally single and basic when consequent on pneumonia, whereas embolic abscesses are often small and multiple and may be found in any part of the lung. Abscesses due to extension from adjacent disease are generally solitary, and are often large and irregular. The walls of acute abscesses are generally formed of congested and œdematous lung tissue, or of a zone of unresolved pneumonia. Since acute abscesses commonly rupture quickly into a bronchus, a fibrous capsule is unusual, but in chronic abscess there is often considerable fibroid change in the neighbouring lung tissue. The pleura may become involved over superficial abscesses, leading to empyema, or to pyo-pneumothorax if rupture follows.

Symptoms.—Abscess may develop insidiously, with comparatively slight symptoms. More commonly they are an intensification of those due to the primary or antecedent condition. The patient often appears seriously ill, the fever becomes of septic type, remittent or intermittent in character, and of a high range. Rigors and sweating are common. The pulmonary symptoms at first may be only slight cough with scanty muco-purulent expectoration. Dyspnœa may be present and pain of acute character develops if the pleura is involved. Hæmoptysis occurs in 70 per cent. of cases of abscess. A considerable leucocytosis, up to 20,000 or 30,000 may be found, and occasionally the breath may be offensive, even before rupture into a bronchus occurs, followed by the sudden expectoration of a large quantity of pus. The pus is sometimes unpleasant or offensive-smelling, but has not the extreme fetor of gangrene. Microscopical investigation will demonstrate the presence of pulmonary debris, especially elastic tissue, together with pus cells and micro-organisms. After the expectoration of the pus, the temperature usually falls and the general condition of the patient is much improved, though cough and expectoration persist. In chronic cases after rupture the temperature may become irregular and periodic, a few days of normal temperature being followed by a period of fever and later by increased expectoration. The physical signs in a deep-seated or small abscess are often inconspicuous, and comprise slight dullness over a small area, weak breath-sounds and possibly a few râles in the surrounding infiltrated or œdematous lung tissue. With a large or a

superficial abscess, the signs before rupture may be those of consolidated or collapsed lung. After evacuation occurs, the characteristic signs of excavation usually develop at once. In multiple embolic abscesses the signs are usually those of disseminated broncho-pneumonia.

Complications and Sequelæ.—The commonest complication is dry pleurisy. This may progress to empyema, or to pyo-pneumothorax, if rupture into the pleura occurs. In some cases mediastinitis or pericarditis may develop. Gangrene is described, but is a rare sequel. Metastatic abscesses may be produced in other parts of the body, especially in the brain, and meningitis is a rare and serious complication. The most important sequelæ are fibrosis of the lung, with bronchiectasis, pleural adhesion, and rarely indurative mediastinitis.

Diagnosis.—This is difficult before rupture, but abscess may be suspected from the gravity of the symptoms in relation to the history and signs, especially if leucocytosis and fetor of the breath are present. X-ray examination may be helpful, by demonstrating a localised shadow before rupture, and excavation afterwards, and also by establishing the situation of the abscess. A fluid level can often be seen in films taken in the erect position. The sudden expectoration of pus, followed by retrogression of symptoms and signs of excavation is very suggestive of abscess. After rupture has occurred the differential diagnosis has to be considered from:

1. *Interlobar empyema.*—This may be very difficult or even impossible. In this condition the signs are generally most marked in the region of an interlobar septum, there may be some cardiac displacement, and the sputum, though purulent, does not contain elastic tissue.

2. *Bronchiectasis.*—The history, the characteristic cough and sputum, and the variation of the physical signs with the state of the cavity usually suffice to distinguish this condition. An X-ray examination after lipiodol or neo-hydriol will distinguish in doubtful cases, since they do not as a rule enter the abscess cavity and the appearances in bronchiectasis are characteristic.

3. *Gangrene of the lung.*—The distinction is not always easy in acute abscess, since the two processes are closely related. The extreme gravity of the patient's general condition and the horrible fetor of the breath and sputum are the most characteristic features of gangrene.

4. *Tuberculous excavation.*—The history, the distribution of the signs, and the characters of the sputum, including the presence of tubercle bacilli, are the distinguishing indications.

5. *Purulent bronchitis.*—The history, the widespread physical signs, and the absence of elastic tissue from the sputum usually serve to establish the diagnosis, and lipiodol or neo-hydriol investigations may be helpful.

In multiple or pyæmic abscesses, it is often impossible to recognise the condition, though it may be suspected from the severity of the symptoms and signs. In any doubtful case an X-ray examination or tomography should be carried out, if the condition of the patient permits. The possibility of malignant growth as a cause of abscess should be borne in mind and, when necesssary, bronchoscopy as well as lipiodol investigation carried out. Exploratory puncture as a means of diagnosis is dangerous and should be avoided.

Prognosis.—The prognosis, though grave in many cases, is better than

might be anticipated. Many of those in which rupture into a bronchus occurs recover. Death is inevitable in the pyæmic cases.

Treatment.—(1) *Medical.*—In acute abscesses medical measures should be employed, since in a considerable proportion of cases, recovery may occur after rupture, especially when the abscess is in the upper lobe. Before rupture the treatment should be similar to that for acute pneumonia. After rupture, evacuation should be promoted by "tipping," or postural drainage. The Nelson bed is of great value in this connection when the relation of the abscess to the nearest patent bronchus has been determined by X-ray examination. Expectorant drugs and antiseptics, such as creosote, should be employed. Antiseptic inhalations may also be used on a Burney-Yeo mask, as for bronchiectasis, or creosote vapour baths may be given. In like manner intratracheal injections of menthol, guaiacol and olive oil have been employed with benefit. In cases with spirochætes, treponemata and anaerobic organisms in the sputum, intravenous injections of salvarsan or neo-arsphenamine may be administered with benefit.

(2) *Surgical.*—If spontaneous rupture does not occur after the abscess has become localised and encapsulated, operation is indicated in order to prevent the walls becoming thick. Repeated bronchoscopic aspiration is sometimes employed after rupture, and at times gives satisfactory results. If, after rupture, there is not satisfactory progress towards cure within 6 weeks, clinically and radiologically, surgical treatment should be considered. Thoracotomy and open drainage is the operation generally employed. This is now usually carried out in two stages: (*a*) a preliminary exposure of the pleura by rib resection and packing with gauze, to ensure adhesion of the pleura; (*b*) some days later the abscess is opened along the course of an exploring needle. Artificial pneumothorax has been recommended, especially in deep or centrally placed abscesses. There is a risk of rupture into the pleura, more particularly when re-expansion of the lung is permitted. For this reason, this form of treatment is rarely advisable. Phrenic evulsion may aid in the evacuation of a chronic abscess. either alone or after thoracotomy. Pneumolysis, lobectomy, and thoracoplasty are also used in the treatment of chronic abscess. Lobectomy seems likely to be the most satisfactory in chronic cases in which it is practicable.

GANGRENE OF THE LUNG

In this condition localised or diffuse areas of lung tissue undergo putrefactive necrosis.

Ætiology.—*Predisposing causes.*—These include old age, over-indulgence in alcohol, general debility, diabetes and insanity. In certain rare cases, especially after broncho-pneumonia complicating measles, gangrene of the lung is met with in children.

Exciting causes and associated conditions.—These are, in the main, identical with those of pulmonary abscess (see p. 1183). In addition, the pressure of aneurysm or of new-growth on branches of the pulmonary artery may lead to gangrene. The causal organisms are also very similar to those found in abscess of the lungs, and include staphylococci, streptococci, sarcinæ, the *Micrococcus tetragenus*, the *Bacillus coli communis*, the *B. pyocyaneus*, the

B. fusiformis with its associated spirochæte, and various anaerobes. In some instances acid-fast bacilli, classed as streptothricæ, occur. Some of these organisms yield putrefactive products, with the liberation of phenol, indole and skatole compounds in the lung.

Pathology.—It is not quite clear what are the factors determining whether abscess or gangrene occurs in an infected area of lung. Doubtless the general resistance of the body, the degree of local vascular disturbance, and the virulence of the infecting organisms all play their part. Laennec first described the two varieties of gangrene, the circumscribed and the spreading or diffuse. Around the former there are indications of a line of demarcation, formed by congested lung tissue, which may present the appearance of red hepatisation. The surrounding lung tissue is invariably somewhat œdematous. The gangrenous area is soft and pulpy, and its colour varies from reddish-brown to greenish-black. As the necrosis advances, putrefactive liquefaction occurs, with the formation of a horribly reeking fluid, containing shreds and masses of necrotic lung tissue. When this is discharged, excavation results, and isolated vessels may be seen running across the resulting cavity, the walls of which are rough and covered with fetid pus. The diffuse variety of gangrene is less common; there is no attempt at a zone of demarcation, and the whole of a lobe or of one lung may be affected. In both forms, the overlying pleura is intensely inflamed, and empyema or pyo-pneumothorax may be produced.

Symptoms.—These are similar to those occurring in abscess of the lung, but are more acute. The patient is desperately ill, rigors are more common and sweating is more profuse. The breath has a peculiar fetor, which, on account of the presence of the skatole group of putrefactive products in the gangrenous lung, has an almost fæcal odour. The sputum is intensely offensive, and on standing separates into three layers, similar to those of the expectoration in cases of bronchiectasis. Elastic tissue is usually present, but it may undergo rapid disintegration. Hæmoptysis is not infrequent and may prove fatal. In rare cases gangrene is not accompanied by fetid expectoration, especially when developing in the insane, in young children, and in diabetics, or after pulmonary embolism. The physical signs closely resemble those present in cases of pulmonary abscess, and are those of consolidation before liquefaction occurs, and of excavation afterwards. The signs of the antecedent condition such as bronchiectasis, aneurysm, or malignant disease may also be present.

Complications and Sequelæ.—These are similar to those met with in pulmonary abscess, but owing to the rapid course and greater fatality of gangrene, they are not so common. Cerebral abscess may occur.

Course.—The course is usually rapid, unless the diseased area is small and circumscribed. In rare cases of localised gangrene of small extent, resolution and subsequent fibrosis occur.

Diagnosis.—The differential diagnosis is as for pulmonary abscess, the distinguishing features being the extremely critical condition of the patient and the revolting fetor of the breath and expectoration. X-ray examination may give great assistance if the patient's condition permits it to be made.

Prognosis.—This is always extremely grave, though a few cases of localised gangrene recover spontaneously. The prognosis is improved by

early operation in suitable cases. The outlook is said to be worse if the condition is apical, and diffuse gangrene is invariably fatal.

Treatment.—Operation is indicated when the general condition of the patient permits, if the gangrenous area can be localised by physical signs or X-ray examination. Exploratory puncture should not be carried out. The other operative procedures are similar to those for abscess of the lung. Operation is contra-indicated in cases of diffuse gangrene. The medical treatment is in all respects similar to that for pulmonary abscess. Injections of neo-arsphenamine, in doses of 0·3 g., have given good results, especially in cases due to fuso-spirochætosis.

PULMONARY FIBROSIS

Synonyms.—Fibroid Disease of the Lung; Chronic Interstitial Pneumonia; Cirrhosis of the Lung.

Definition.—Pulmonary fibrosis is a late sequel of many acute and chronic inflammatory or irritative processes affecting the bronchi, lungs and pleuræ. It is therefore rather of pathological than of clinical interest, and in no sense constitutes a separate disease, although the end-results are remarkably similar in different forms. It is described here partly in deference to tradition, and partly to point out the methods of diagnosis between the various causes producing such strikingly similar effects.

Ætiology.—(1) The commonest cause is pulmonary tuberculosis, particularly the fibroid and fibro-caseous varieties. (2) The group of pneumokonioses contributes a considerable number of cases, and possibly some varieties of gas poisoning may induce fibroid changes. (3) Bronchopneumonic processes, particularly the forms associated with measles and whooping-cough, may be followed by widespread fibrosis, especially in children. (4) Although fibroid induration is commonly described as a sequel of lobar pneumonia, this disease is one of the rarer causes. (5) Localised fibrosis may occur around any circumscribed pulmonary or bronchial lesion, such as that produced by syphilis, leprosy, glanders or streptotrichosis. Similarly it occurs about infarcts, pulmonary abscesses and parasitic cysts. (6) Chronic venous congestion, if prolonged, leads to fibroid change, which is referred to as "brown induration." This is usually of moderate degree and does not affect the clinical manifestations. (7) Chronic pleural affections, particularly those leading to adhesions or causing pulmonary collapse, may induce fibroid changes within the lung, and these forms are described as "pleurogenous cirrhosis." (8) Any condition causing obstruction of a bronchus and leading either to collapse or to bronchiectasis may, if long continued, cause fibrosis of the corresponding lung area. Among such may be mentioned inhaled foreign body, new-growth, cicatricial contraction and thoracic aneurysm.

Pathology.—The fibroid overgrowth may be: (1) Massive or lobar; (2) localised or insular; (3) peribronchial; and (4) reticular.

Any part of the connective tissue framework of the lungs and bronchi may contribute to the fibrosis. In the massive form, which generally affects the whole or the major part of a lobe or even of one lung, the appearances in cases due to tuberculosis differ from those due to other causes. In the

tuberculous variety the primary distribution is usually apical, and evidence of other tuberculous processes may be apparent in the form of large or small dried-up cavities, inspissated caseous material or calcareous masses enclosed in fibrous strands. In non-tuberculous processes, the early localisation is commonly basic, and although the primary cause may be obvious in the form of bronchial obstruction or some pleural condition, this is not always the case. On the other hand, non-tuberculous processes may involve the upper lobe primarily and fibroid tuberculosis may fall with special stress upon the lower lobe. In both forms of fibrosis, bronchiectasis may result, although this is more common in the non-tuberculous cases. Apart from the special tuberculous lesions, the end results are very similar in both forms. The affected area of the lung is shrunken and often devoid of air except for that in the bronchi and in the cavities. It is dark in colour, very firm and hard. On section it presents a mottled appearance owing to the strands of blue-grey fibrous tissue traversing it, contrasting with the pigmented, condensed, airless lung tissue. The fibroid area may be honeycombed by cavities or may present one large excavation, due either to tuberculous cavitation or to bronchiectatic dilatation. There is nearly always thickening and adhesion of the pleura. The contraction of the abnormal fibrous tissue leads to marked displacement of the heart and mediastinum.

The localised form is commonly due to healed tuberculous processes at an apex. There may be simple puckering with or without pleural thickening and adhesion, or a dense mass enclosing dried-up caseous matter or calcareous spicules. In bronchitic or broncho-pneumonic processes a patchy fibrosis may occur, described as insular fibrosis by Fowler.

Reticular fibrosis is a rare condition in which the fibrous tissue in the interlobular septa seems to become increased as well as that around the bronchi. It is at present only of pathological interest.

Symptoms.—The symptoms of pulmonary fibrosis are, in the main, expectoration and dyspnœa together with those of the primary affection. In the non-tuberculous cases, bronchiectasis is so frequently associated that the symptoms and signs found are practically those of this condition. Even in tuberculous cases, some degree of bronchial dilatation is the rule, although the sputum is rarely offensive. The cough is generally periodic and associated with change of posture. The expectoration is abundant, and if bronchiectasis is present, it has the usual characteristic features. The dyspnœa is proportional to the extent of lung involved. It may be extreme in the later stages, when the heart becomes embarrassed and begins to fail. Fever is usually absent, except when complications occur.

The patients are generally spare, although nutrition may sometimes be well maintained until late. They may show signs of deficient aeration in duskiness, cyanosis and congested cheeks. Polycythæmia of some degree is the rule. Clubbing of the fingers is almost constant. Evidence of contraction is generally forthcoming in the flattening and retraction of the affected side, with the dropped shoulder and compensatory spinal curvature. Movement is greatly restricted, contrasting with the increased expansion of the other side. The cardiac impulse is sometimes much displaced, especially in left-sided cases, when it may be in the left posterior axillary line or even under the angle of the scapula. In right-sided cases, it is drawn

to the right of the sternum, even sometimes under or outside the right nipple. Vocal fremitus is usually diminished and percussion gives dullness of varying degree over the fibroid area, while the unaffected parts may be hyper-resonant from "compensatory" emphysema. The diaphragm may be drawn up, and the liver or stomach correspondingly displaced. The breath-sounds are often weak or inaudible unless there is bronchiectasis or cavitation, when the characteristic signs of these conditions can be recognised. The vocal resonance is diminished if there is much pleural thickening, increased if cavities are present. Adventitious sounds may be entirely absent, and when present vary from rhonchi and bubbling râles to coarse metallic râles, according to the presence or absence of excavation. X-ray examination gives useful confirmation, showing displacement, excavation and pleural thickening.

Course.—The course is invariably chronic, and may extend to years, even ten or twenty.

Diagnosis.—The diagnosis is usually easy. The evidence of contraction and of mediastinal displacement towards the affected side, especially if signs of cavitation are also present, is highly suggestive. In the absence of the cavitation some difficulty may arise in regard to chronic pleural effusion or empyema. In the earlier stages the contra-lateral displacement of the cardiac impulse should prevent any mistake, but where partial absorption has occurred, this may be very slight or absent. In such cases an exploratory puncture or an X-ray examination may be helpful.

When the diagnosis of pulmonary fibrosis has been made, the differentiation of the cause is an essential to prognosis and treatment. If the condition is apical, there is a presumption in favour of tuberculosis; if basic, some other cause is more probable. Repeated examinations of the sputum should be made for tubercle bacilli, and if these prove negative, X-ray examination may reveal some cause such as new-growth, aneurysm or even foreign body. In some cases a careful consideration of the history may afford a clue to the diagnosis.

Prognosis and Treatment.—These depend upon the primary condition, but in most cases the latter is mainly symptomatic.

PNEUMOKONIOSIS

Synonyms.—Pneumonokoniosis; Dust Disease of the Lung.

Definition.—Pneumokoniosis comprises all the pathological changes induced in the bronchi, lung and pleuræ by the inhalation of dust particles.

Ætiology.—*Predisposing causes.*—Pneumokoniosis is one of the occupational diseases. It is practically limited to men, and usually develops between the ages of 25 and 40. Defective ventilation, bad hygienic conditions and alcoholism promote its incidence.

Exciting causes.—Various forms of dust, both inorganic and organic, serve to produce pneumokoniosis, and in general the harder and more gritty the particles, the more marked are the changes induced. Organic forms of dust lead especially to bronchitic changes, the inorganic forms to pulmonary fibrosis.

The following varieties are recognised:

1. *Anthracosis* from coal dust (coal-miners' phthisis).

2. *Siderosis* (silico-siderosis), from the inhalation of fine particles in tin, copper, lead and iron miners, and in grinders of steel goods (grinders' rot).

3. *Silicosis* or chalicosis, met with in workers in quartz, gannister and slate quarries, also in potters (quarts-miners' phthisis, and potters' asthma). Gold-miners' phthisis, the most serious form of pneumokoniosis, and especially prevalent in the South African gold mines, is due to the fine dust caused by the rock drills.

4. *Byssinosis*, a rare variety, is met with in cotton workers, felt-hat makers, and the employees in shoddy mills.

5. *Asbestosis.*—A condition found occasionally in those working in the manufacture of asbestos articles. Asbestos is composed of compound silicates of iron and magnesium.

Pathology.—The lungs of persons living under rural conditions are practically free from deposited pigment. A certain amount of carbon is invariably present in the lungs of town-dwellers, giving them a dark-grey mottled appearance, but producing no pulmonary fibrosis. In coal-miners this occurs to such an extent that the lungs are black (anthracosis), although even here little fibrosis occurs, except in miners of hard coal or anthracite. In siderosis and silicosis, fine sharp particles of metallic oxides or silica are deposited in the lung tissue. According to Stewart, siderosis is in effect silico-siderosis, the damaging agent being silica inhaled at the same time. In asbestosis, curious irregular discoid structures of golden yellow colour and containing iron, now called "asbestosis bodies," are found in the lungs and in the sputum. There is also much fibrosis in pneumokoniosis, and tuberculosis is liable to be a later development.

It is generally accepted that these particles are conveyed to the bronchi and alveoli by inhalation. In normal breathing, most of the coarse particles are detained in the nose, and are discharged with the nasal mucus, whereas in mouth-breathers they readily gain access to the trachea and bronchi. Even then, the coarser particles may be discharged, in the expectoration through the agency of the ciliated epithelium, but, owing to the catarrhal processes induced by the irritation of the inhaled dust, this epithelium may be desquamated and the absorption of the particles is promoted. As a further consequence of this initial bronchitis, the finer particles may reach the alveoli, and passing between the epithelial cells, gain access to the tissue spaces, or in some cases they may be taken up into special "dust cells." In silicosis, particles of crystalline silica become deposited in the connective tissue, and chronic peribronchial and perialveolar fibrosis develops. The bronchial glands also become enlarged by the deposition of similar particles conveyed by the lymphatics. Other changes more or less constantly present are emphysema, pleural adhesion and bronchiectasis.

The relationship to tuberculosis has been much debated. It is now established that pneumokoniosis is non-tuberculous in origin, and that it may remain so throughout its course. On the other hand, certain forms undoubtedly favour the development of tuberculosis. In England and Wales coal-miners suffer less from tuberculosis than do all other males. On the other hand, gold-miners are extremely liable to it. It would appear that the determining factor is the presence of particles of silica. Silicates, as

in clay, do not induce tuberculosis. Workers in freestone develop this disease, limestone workers do not. Slate quarries do not acquire tuberculosis very readily, while metalliferous miners working in quartzite very frequently suffer from it. The Miners Phthisis Bureau recognises two types of silicosis. (1) Simple silicosis, the damage found being due to dust alone. It is non-progressive if exposure ceases. (2) Tuberculo-silicosis, in which most of the damage is due to dust, and tuberculosis is secondary. Haldane and Mavrogordato demonstrated that particles of coal are absorbed by the "dust cells" whose movements are thereby stimulated, with the result that they appear in the black spit, which is therefore a healthy sign. The particles of silica are also absorbed by these "dust cells," but no stimulus to their movement is induced and they remain *in situ*. Kettle and Gye have shown that a silica colloid is slowly formed, which leads to breakdown of the tissue defences and thus favours the activity of tubercle bacilli.

Post mortem, the lungs are generally firm and pigmented, the colour varying with the cause, being black in anthracosis, reddish-brown in siderosis, and greyish-black in silicosis. The pleura is generally adherent, especially at the bases. On section the lungs are firm, and often gritty. Small hard nodules may be felt with the finger. Fibroid changes are especially marked in silicosis. The bronchi are inflamed and sometimes dilated. Soem degree of emphysema is usually apparent. If tuberculous lesions are also present, these vary from fibroid areas to miliary nodules. Destructive processes resulting in cavitation may also be seen. Microscopically, the alveolar walls are thickened, the connective tissue is everywhere found to be increased, the "dust cells" may be seen in the connective tissue or in the alveoli, and particles of pigment or silica are found widely deposited in the connective tissue cells.

Symptoms.—The onset is insidious, bronchial irritation and cough, especially in the morning, may be the first indications, but increasing shortness of breath and debility are frequently early symptoms. The expectoration, at first scanty and mucoid, becomes more abundant and may present characteristic features as in the "black spit" of anthracosis. Tinging of the sputum and later hæmoptysis occur, but these suggest the possibility of superadded tuberculosis. The patient may appear healthy and be but little troubled except by the shortness of breath, but later emaciation and an appearance of premature old age are not uncommon.

The physical signs are not characteristic; at first they are simply those of persistent bronchitis, then emphysematous changes may become apparent. Later, signs of fibrosis appear, very similar to those described in the preceding section. Even when tuberculosis develops the signs are often but little characteristic, and repeated sputum tests may be necessary to establish the diagnosis. Examination by X-rays may be helpful; at first there is an increase in the reticulation and later nodulation, somewhat like that of miliary tuberculosis. At a still later stage, the nodules become larger, and there is increased fibrosis. The changes characteristic of tuberculosis may be super-added.

Complications and Sequelæ.—The most important complication is tuberculosis, which forms the terminal stage of many cases of silicosis. This may be suspected when fever, night sweats, hæmoptysis or emaciation develop. Bronchiectasis of considerable degree sometimes results as a

consequence of the fibrosis, and leads to the symptoms and signs characteristic of that condition.

Course.—This is progressive, unless the sufferer is removed from the exciting causes. Anthracosis runs a very chronic course, siderosis somewhat less so, while gold miners only live a few years (5 to 6—Oliver) after the onset of the disease.

Diagnosis.—The diagnosis can usually be made from the history of shortness of breath, cough and expectoration, developing in a worker in a dusty occupation. In the early stages, cigarette-smoker's cough and bronchitis may give rise to difficulty. In the later stages, the possibility of a primary fibroid tuberculosis has to be considered.

Prognosis.—This is unfavourable except in anthracosis. Lyle Cummins suggests that the finely divided carbon particles absorb the toxins of the tubercle bacillus. If recognised early, and if the patient is taken from the dusty conditions, recovery may be anticipated. The development of tuberculosis affects the outlook very gravely.

Treatment.—*Prophylactic.*—Every means should be adopted to avoid the dusty conditions leading to the disease. Mines should be well ventilated, and respirators should be worn where practicable in dusty occupations. Factories and workshops should be provided with apparatus to draw away dust. Sprays or jets should be used with drills to moisten the dust produced.

Curative.—Directly the condition is diagnosed, the patient should be advised to change his occupation. Nutrition should be kept at a satisfactory level. Symptoms and associated conditions, such as bronchitis or tuberculosis, should be treated on general principles.

PULMONARY TUBERCULOSIS

Synonyms.—Phthisis; Consumption; Decline.

Pulmonary tuberculosis embraces all the abnormal conditions induced by infection of the lungs, pleuræ and bronchial glands with the tubercle bacillus.

Ætiology.—Predisposing Causes.—Age.—The maximum age incidence is between the 15th and 45th years, although the disease may be encountered at any age. Senile tuberculosis is more common than is generally recognised.

Sex.—The disease is more frequent in males, but between the ages of 5 and 15 the female sex shows a preponderance.

Heredity.—Pulmonary tuberculosis certainly occurs with undue frequency in certain families. Since the direct transmission of the tubercle bacillus to the infant is extremely rare, two explanations seem possible—(1) Children born of tuberculous stock may inherit an increased susceptibility or diminished resistance, the tuberculous diathesis; or (2) they may contract tuberculosis on account of their exposure to massive infection in early life.

Race.—Differences in racial susceptibility probably depend upon the degree of inherited resistance acquired by the race from infection of previous generations. Native races suffer severely when first exposed. In Europe the Irish are particularly susceptible, whereas the Jews are relatively immune.

Climate.—Tuberculosis occurs in all climates. The prevalence of strong

rainy winds and defective subsoil drainage may tend to increase its incidence.

Occupation.—The highest mortality from tuberculosis occurs in England amongst the workers in dusty occupations, thus Cornish tin miners head the list. On the other hand, coal miners are notably free from the disease. Any conditions leading to overwork or to underfeeding increase the liability to tuberculosis.

Environment.—Overcrowding, defective sanitation, dampness, dirt, lack of sunlight and insufficient ventilation are most potent factors in the spread of the disease, causing both lowering of the resistance and increased facilities for direct infection.

Trauma.—Trauma, involving the chest-wall, may be followed by active pulmonary tuberculosis. This is probably because the injury leads to activity of previously arrested disease, rather than to fresh infection at a spot of lowered resistance.

Gassing.—In certain cases the inhalation of poison gases causes rapid activity and spread in latent disease, or it may possibly prepare the ground for reinfection, but it is not a factor of great ætiological importance.

The influence of other diseases and conditions.—The following diseases predispose to the development of pulmonary tuberculosis: measles, especially when complicated by broncho-pneumonia, whooping-cough, influenza, pneumokoniosis, alcoholism, diabetes, syphilis, congenital heart disease and insanity. Tuberculosis may manifest itself for the first time during prolonged lactation or after repeated pregnancies; when previously existent it often remains quiescent during pregnancy, but it may spread rapidly after childbirth. Contrary to the usual belief, pulmonary tuberculosis not infrequently coexists with mitral stenosis. Cases apparently following pneumonia, pleurisy or bronchitis are usually tuberculous from the onset.

Exciting Causes.—The causal organism is the *Bacillus tuberculosis*, discovered by Koch in 1882. It exists in four main forms, human, bovine, avian and reptilian; only the two former usually occur in man, but avian infection has been recorded. The human type is found in over 97 per cent. of pulmonary tuberculous lesions, though a higher proportion of the bovine type has been found in Scotland. In glandular tuberculosis up to the age of 5 years, over 80 per cent. of the bacilli isolated conform to the bovine variety. In tuberculosis of bones and joints up to the same age, 29 per cent. of the cases are of bovine origin.

The bacilli may gain access to the body by inhalation, by alimentary ingestion, through the tonsils, through the skin, or possibly, in rare instances, by hereditary transmission. It is probable that in the majority of cases of pulmonary tuberculosis in adults, the organisms are carried direct to the lungs in the inspired air, and Ghon showed that in children, who had died of tuberculosis of the lungs, a primary focus was present in the lungs in 92·4 per cent. As, however, extensive tuberculous lesions are frequently found in the bronchial glands in cases of pulmonary tuberculosis, it is believed by some that the glands are primarily affected, and that the bacilli pass from them to the lungs, either against the lymphatic flow or in the blood stream. Calmette and others have demonstrated that the bacilli may gain access to the bronchial glands from the alimentary tract through the

thoracic duct, or from the tonsils through the cervical and mediastinal glands. Cases have been recorded in which primary cutaneous infections have been followed later by active pulmonary tuberculosis. Direct transmission of the tubercle bacillus is believed to occur only when the mother is suffering from advanced tuberculosis, and even then is of great rarity.

The incubation period tuberculosis of is uncertain, owing to the difficulty in determining when infection takes place. It is now believed by many authorities that the majority of individuals are originally infected in infancy or early childhood, either from the ingestion of tuberculous milk, or by the inhalation of bacilli from dried sputum. Pulmonary tuberculosis is thus regarded as a late manifestation comparable with the tertiary stage of syphilis. On this hypothesis, active pulmonary disease in adult life may result either from reinfection or from the activation of a dormant lesion in the body. As the organisms found in early life are frequently of the bovine type, whereas in pulmonary tuberculosis they are almost invariably of the human variety, it is probable that reinfection is the more common, since mutation of type has not so far been proved.

Provided that the proper precautions are taken, the risk of infection from adult to adult is not great, and only exists in " open " cases of tuberculosis, *i.e.* in cases with tubercle bacilli in the sputum. The occurrence of conjugal disease, which is less common than might be expected, has been explained by mating of those with hereditary diathesis.

Pathology.—The earliest lesion in the lung is the formation of tubercles, whose structure is described in the general article on tuberculosis. They usually appear first near the apex. This may be due to the relative immobility of this portion of the lung, possibly as the result of calcification of the first costal cartilage (Freund), but in some cases the bacilli may spread from the cervical to the supraclavicular glands and thence to the adjacent lung. In some cases the earliest lesion is found in the subclavicular region well below the apex. It may commence in a subacute manner. In such cases, an area of localised deposit may be seen on radiological examination—known as Assmann's focus (Redecker's "*früh infiltrat*"). The initial deposit is usually in or around the small bronchioles of the third to fifth degree (Hirschfeld's bronchioles). The inflammatory swelling of the bronchioles obstructs their lumen, leading to collapse of the alveoli beyond and the formation of bronchopneumonic areas. At the same time peri-bronchiolar inflammation develops. In children there is, in the majority of cases, a primary lung focus (Ghon's focus), with secondary deposits in the bronchial glands.

Secondary Changes.—1. *Caseation.*—The tubercle is avascular, and owing to this, and possibly also to the action of tubercle toxins, coagulation necrosis and fatty degeneration frequently ensue. This combined process is known as caseation and results in the formation of a structureless, cheesy mass. Further changes may now occur, either softening, with the development of a " cold abscess " filled with tuberculous " pus," or calcification, with the subsequent formation of gritty masses known as " pneumoliths."

2. *Cavitation.*—Cavities result from the liquefaction of caseous areas, and the expectoration of the resulting debris. They may be no larger than a pea, or may occupy the whole of one or more lobes. A recent cavity has an irregular outline, with rough, shaggy walls and a vascular line of demarcation. It is often traversed by trabeculæ, formed by bronchi and vessels

which may be partly or completely obliterated, while sometimes the trabeculæ consist of condensed lung tissue which originally separated adjacent cavities. In chronic cases, the cavity is surrounded by fibrosed lung tissue forming a pseudo-capsule, and its interior becomes lined by a thin, smooth, false membrane. Small aneurysms may be found, arising either from vessels running in the walls or in the trabeculæ of the cavity, the former being the more common. In some cases, where hæmoptysis has occurred, rupture of such an aneurysm is the cause.

3. *Fibrosis.*—Reactive changes in the lung stroma lead to the formation of fibrous tissue. This may occur early or after caseation has taken place. Such changes are often classified as productive, whereas infiltration and the earlier reactive changes are referred to as exudative.

In the majority of deaths from all causes, old tuberculous lesions are found post mortem near the apex of one lung. These consist of small nodules of arrested disease, with thickening and dimpling of the adjacent pleura.

Dissemination in the Lungs.—The disease may spread from the primary peri-bronchial deposit—(*a*) By direct infiltration; (*b*) By the peri-bronchial lymphatics and capillaries, leading to a racemose appearance or to peri-bronchial fibrosis; (*c*) By the subpleural and interstitial lymphatics, with localised miliary dissemination; (*d*) By inhalation into a bronchus of tuberculous material, which is then carried to other parts of the same or to the opposite lung—this not infrequently happens after hæmoptysis and in cavitation; (*e*) By the blood vessels, *e.g.* generalised miliary tuberculosis may result from erosion of a caseous tubercle into a vein.

The pathology of the clinically distinguishable forms of pulmonary tuberculosis will now be described.

1. Acute Miliary Tuberculosis.—A primary caseous focus may be discovered at the apex of one lung, in the bronchial glands, or at some distant spot in the body. Local erosion of a vein may be found, accounting for the dissemination of the disease. The lungs are usually studded with minute grey tubercles, the smaller ones requiring a hand lens for their recognition. In very acute cases death occurs before any secondary broncho-pneumonic changes take place. Miliary tuberculosis may develop as a terminal event in chronic fibro-caseous or fibroid tuberculosis. The tubercles are then found in large numbers around the old foci of disease, but to a less extent in the more remote portions of the lung.

2. Chronic Miliary Tuberculosis.—The lungs are studded uniformly with firm nodules varying in size from one to several millimetres in diameter. They are grey or white, project from the cut surface of the lung, and in some cases are calcified. There may be, in addition, a diffuse fine fibrosis. Miliary tubercles are at times found scantily distributed in the spleen, kidneys and liver. Not infrequently there is evidence of terminal acute miliary tuberculosis involving the brain and meninges.

3. Acute Caseous Tuberculosis.—Large areas of consolidation form rapidly, which differ histologically from the common chronic tuberculous broncho-pneumonia in that the alveolar exudate is more definitely inflammatory and contains fibrin. In the rare lobar cases, the rapid caseation and the presence of tubercle bacilli show that the caseous pneumonia is a specific process. Firm yellowish patches, which may be confluent, are seen,

usually scattered throughout both lungs. The affected areas are airless and sink in water. Softening is generally present in varying forms up to actual cavity formation, which may be extensive, involving even a whole lobe.

4. Fibro-caseous Tuberculosis.—This is the commonest variety of the disease; the appearances of the lung vary with the relative preponderance of the caseous and fibrotic changes. The early lesions are miliary or bronchopneumonic, but areas of caseation in varying stages, including cavitation, are almost always present. The older lesions show considerable fibrosis, the strands of sclerotic tissue being pigmented and glistening. The earliest lesion is usually near the apex of the upper lobe at the back, more rarely a little lower and towards the front. The apex of the lower lobe is next affected, and the disease then spreads in the direction of the interlobar septum; the apex of the upper lobe of the opposite lung is next involved (Fowler's law of spread). Pleural adhesions are usually present over the oldest lesions, and in the interlobar fissures. An open cavity, from which infected sputum is discharged, is a danger, being a frequent cause of spread.

5. Fibroid Tuberculosis.—Fibrosis may be localised around a small arrested lesion, or may spread throughout a lung in which caseation or excavation has occurred. One lobe or the whole lung is then contracted and firm. In the interstices of the fibrous tissue, which is usually pigmented, inspissated caseous material, calcareous patches, or cavities are seen. The shrinkage may lead to bronchiectasis, especially in the lower lobes. The overlying pleura is much thickened and adherent, and the mediastinum is drawn over towards the affected side. The opposite lung, or the sound portions of the fibrosed one, may show compensatory emphysema.

The bronchial glands.—The tracheo-bronchial glands are affected in all forms of pulmonary tuberculosis. They are enlarged, sometimes pigmented, and may present miliary, caseous, calcareous or fibroid changes, in some cases primary, in others secondary to the lesions in the lungs.

The pleura.—This, too, is almost constantly affected. The commonest changes are an early dry pleurisy, and a later thickening with adhesions which may completely unite the visceral with the parietal layers. In acute disease or active spread, the pleura may be studded with miliary tubercles, leading to a large serous effusion.

The post-morten appearances of the lesions situated in the other organs, found as complications of pulmonary tuberculosis, are described in the respective sections dealing with them, and include tuberculous meningitis, peritonitis, enteritis and genito-urinary tuberculosis. There is usually atrophy of the skeletal muscles, sometimes lardaceous and fatty degeneration of the liver, and hypoplasia with fatty degeneration of the heart.

Symptoms.—The symptoms fall into three groups (Pottenger)—(1) pulmonary, such as catarrh, expectoration, hæmoptysis and pleurisy; (2) reflex, such as pain, cough and laryngeal irritability; (3) toxæmic, including malaise, tachycardia, pyrexia and loss of weight.

Onset.—The mode of onset is very variable, but certain forms can be recognised.

(*a*) *Insidious*).—The early symptoms may be malaise, anæmia, amenorrhœa, cardiac irritability, progressive loss of weight, and slight rise of temperature, generally towards evening. Cough and expectoration often appear only when the signs in the chest are quite apparent. When there is intestinal

stasis, the cutaneous pigmentation may suggest the diagnosis of Addison's disease.

(*b*) *Catarrhal*—A series of febrile "colds" may usher in the disease, and such a sequence is always suspicious.

(*c*) *Phthisis ab hæmoptoë*.—Hæmoptysis may first draw attention to the lungs. It may be slight, and is then due to early congestion around the focus of infection. If it is more marked, it indicates breakdown of an old arrested lesion, or may afford dramatic evidence of extensive disease which had not been recognised previously.

(*d*) *Laryngeal*.—Hoarseness or aphonia may be the first symptom, but laryngeal tuberculosis is usually secondary to pulmonary disease, although the latter may have been unsuspected.

(*e*) *Gastro-intestinal*.—Anorexia and flatulence often occur early. When they are accompanied by slight loss of weight and pyrexia, the possibility of pulmonary tuberculosis should be suspected.

(*f*) *Pleural*.—Dry pleurisy is a frequent manifestation of latent pulmonary tuberculosis. When a serous effusion develops, its tuberculous character can be determined by laboratory investigations. Pneumothorax, developing in a previously healthy individual is a rare but often serious clinical mode of onset.

(*g*) *Pneumonic*.—"Galloping" consumption often begins with pneumonic manifestations, especially in the young.

(*h*) *Traumatic*.—Pulmonary tuberculosis may follow injury or "gassing," as described under ætiology.

(*i*) *Neurasthenic*.—Neurasthenia may occur as a complication of tuberculosis; but in some cases an initial neurasthenia dominates the picture, and the pulmonary lesion is only detected on careful examination.

(*j*) *Malarial*.—Regular attacks of sweating and fever may occur, especially in those who are or who have been residing in malarial climates, suggesting malaria, but in reality due to tuberculosis.

(*k*) *Associated with other diseases*.—Tuberculosis may follow immediately on an attack of measles, influenza or whooping-cough, especially if complicated by broncho-pneumonia. In some cases it develops at a later period after the acute disease.

(*l*) *Senile*.—In old people an insidious onset is common. The disease may be of bronchitic type, and the signs are often masked by emphysema. There may be little or no rise of temperature.

THE CHIEF SYMPTOMS of pulmonary tuberculosis are—

Cough.—This varies considerably in different types of disease. It may be very slight or absent in generalised miliary tuberculosis, or in any form in the insane. It is sometimes dry, persistent and ineffective, especially in miliary extension in the lungs from an old focus of disease, in bronchial gland tuberculosis, or in pleurisy. When there is associated bronchitis or caseation, the cough is usually accompanied by expectoration, which, if very tenacious, may lead to retching or even to vomiting, particularly in the morning. In laryngeal tuberculosis the cough is husky and frequently painful.

Expectoration.—In early disease there is usually no sputum, and in some cases, more especially in the fibroid type, widespread lesions may be present with practically no expectoration. When caseation is in progress, or when

there is secondary infection with bronchitis, the sputum may be abundant and amount to as much as 20 or more ounces in the 24 hours. It may be clear or mucoid, or thick tenacious muco-pus. If mucoid, it often contains small particles, the size of a pin's head or larger, of yellow caseous material. Nummular sputum may be met with in active caseous disease, especially with excavation. This consists of flat rounded masses of muco-pus, with a somewhat distant resemblance to coins. In tuberculosis the sputum is usually inoffensive, but may have the characteristic sickly odour which is also noticed to emanate from the patient himself (odor phthisicus). If bronchiectasis or gangrene occurs as a complication, the expectoration becomes typically malodorous. Pulmonary calculi or pneumoliths, composed chiefly of calcium carbonate or phosphate, are sometimes expectorated. They vary in size from a pin's head to a pea, are irregular in outline and sometimes branched, being derived generally from the walls of a cavity. Although the occurrence of these does not necessarily indicate fresh activity in the lungs, yet such a possibility should always be suspected, and a careful watch maintained on the temperature during the next few days. In some cases larger pneumoliths, as big as a cherry, may be coughed up, and those are frequently derived from calcified tracheo-bronchial glands. They may give rise to alarming symptoms at once, and be the forerunner of fresh activity in the lungs.

Microscopical examination.—The presence of tubercle bacilli in the sputum is the most decisive test of the existence of this disease. The small yellowish caseous particles should be selected from the sputum, and appropriately stained. If no tubercle bacilli are found, samples from the whole sputum of the 24 hours, concentrated by the antiformin method, can be examined. Droplets collected on a laryngeal mirror by cough induced by it may be examined for the presence of tubercle bacilli, especially in children or in patients who habitually swallow sputum.

Sputum culture by the Loewenstein method may be of value when tubercle bacilli are not found in smears. The cells present are usually of the mononuclear type, either mononuclear leucocytes or altered alveolar epithelial cells. The presence of elastic tissue indicates that destructive pulmonary lesions are in progress. Secondary infecting organisms may be demonstrated by cultural methods.

Dyspnœa.—Slight dyspnœa occurring early in the disease may be due to diminished movement of the diaphragm on the affected side. In more advanced cases the degree of dyspnœa is proportional to the amount of lung tissue involved. In addition, cough and pyrexia play a part in its production. Complications such as pleurisy, pleural effusion, pneumothorax and cardiac failure increase the shortness of breath. It is rare to find orthopnœa even in acute and rapidly spreading disease. In arrested cases the dyspnœa is proportional to the extent of fibrosis.

Cyanosis.—This is not an early symptom of tuberculosis. It is dependent upon the amount of lung tissue involved, but is increased by the coexistence of emphysema or cardiac failure. The typical "hectic flush" of tuberculosis is a vasomotor effect caused by toxæmia.

Pain.—Not every sufferer from tuberculosis experiences pain, even in the acute stages of the disease. The commonest cause of pain is dry pleurisy. When the diaphragmatic layer of the pleura is affected, pain may be referred to the epigastrium or to the corresponding shoulder. In chronic fibroid

phthisis there is frequently a dull, aching pain in the chest, which is more noticeable in damp weather. This is caused by the contraction of the condensing fibrous tissue. Cutaneous tenderness of the chest-wall is met with in some cases of advanced disease, and is probably due to a cachectic neuritis. A "cold abscess" forming along one of the ribs or costal cartilages is a rare cause of localised pain in the chest-wall. Cough may be painful, especially when paroxysmal or frequent, the pain being referred to the costal attachments of the diaphragm and upper abdominal muscles. The sudden occurrence of pneumothorax may cause such severe pain as to induce collapse; but when of more gradual onset no severe discomfort may be experienced. Tuberculous laryngitis may be the cause of very great suffering.

Night sweats.—Although not pathognomonic, night sweats occur more frequently in tuberculosis than in other diseases. They are met with in all stages of active lesions, and may be of great severity.

Loss of weight.—This is often an early symptom. It is most marked in acute disease and in the late stages of chronic fibro-caseous tuberculosis.

Fever.—Pyrexia is one of the most important indications of activity at any stage of pulmonary tuberculosis, although it does not follow that the disease is arrested when there is no fever. During treatment the temperature should be recorded at certain definite hours in the day. (*a*) On waking. The normal mouth temperature at 7 or 8 a.m. is 97° or 98° F. in the mouth, and 97°·2 to 99° F. in the rectum. This temperature should be taken in bed, before eating or drinking. (*b*) At 1 p.m., after the hour's recumbent rest. (*c*) At 6 p.m. (*d*) At 9 p.m., after retiring to bed. The maximum temperature is usually reached between 4 and 6 p.m., but may be delayed to 8 or 9 p.m. In most Continental sanatoria the rectal temperature is taken, and a centigrade thermometer employed. The temperature is dependent upon the extent and the activity of the disease, and upon the amount of exercise taken.

(*a*) In acute miliary tuberculosis it may be continuous or remittent, and the "typus inversus" is not uncommon, the morning temperature being higher than the evening. This is generally regarded as a sign of grave prognosis.

(*b*) In acute caseous tuberculosis the high temperature at the onset is continuous, and the record resembles a pneumonic chart. When caseation occurs it becomes hectic or intermittent, with a daily swing of 4° or 5° F. This is probably due to the action of tubercle toxins, and not to the presence of a secondary infection.

(*c*) In chronic fibro-caseous tuberculosis there is no characteristic temperature record. There may be only a very slight rise occurring at intervals of a few days. On the other hand, the patient may be afebrile while resting, but febrile when ambulant (Stage 2. Inman's classification). Further an afebrile ambulant patient may over-exert himself, and by excessive auto-inoculation develop a sharp rise of temperature which subsides in a few days with rest. The temperature chart is thus a guide to prognosis and to treatment, and if acute miliary tuberculosis or caseation occurs, a typical temperature variation ensues.

(*d*) In fibroid tuberculosis the temperature is usually normal, unless excessive auto-inoculation results from exercise, or the disease advances. The occurrence of hæmoptysis may have a very definite effect upon the temperature. In some cases it is not followed by pyrexia, but if the inhaled blood leads

to a hæmoptoic bronchitis, there may be a slight degree of fever lasting for a few days. When a definite and persistent pyrexia follows, it usually indicates activity around an old focus of disease, or fresh spread by inhalation of blood containing tubercle bacilli to distant parts of the lung.

A premenstrual rise of temperature may occur; but as it is also met with in healthy women it is not pathognomonic.

Hæmoptysis.—Hæmoptysis occurs at some stage of pulmonary tuberculosis in about 50 per cent. of all cases. With early lesions the sputum is only streaked. This may result from the congestion of tuberculous bronchitis, or from a small area of collapse or broncho-pneumonia. In the pneumonic or broncho-pneumonic forms rusty sputum may be seen. Profuse hæmoptysis generally occurs in chronic disease; but it is occasionally met with in acute caseous forms. Recovery may take place after coughing up 2 or 3 pints, or death may ensue rapidly from suffocation before any considerable quantity of blood has been expectorated. After the cessation of bleeding the sputum may be blood-stained for several days, the colour becoming darker. The source of profuse hæmoptysis is generally an aneurysm of a branch of the pulmonary artery lying in a cavity or in a fibroid lung, although occasionally ulceration without previous aneurysm formation may occur. In the majority of cases hæmoptysis begins while the patient is lying down or resting, so that exercise or work are not frequent exciting causes.

The patient notices a salt taste, feels a warm gush in the mouth, and then expectorates the blood. He is usually greatly alarmed, flushed and sweating, with rapidly beating heart. The blood at first is as a rule bright and frothy but some clots may be present; later it is mixed with muco-purulent expectoration, in the form of clots or streaks.

Circulatory system.—The heart may be small, but the right side often hypertrophies in chronic fibroid cases. Tachycardia may be due to nervousness, but when constant it generally indicates active disease or over-exertion on the part of the patient. The blood pressure is usually low in the stages of activity, and a steady rise during treatment is a favourable sign. If tuberculosis is coexistent with other diseases, such as atheroma, which raise the blood pressure, higher readings are naturally obtained.

The blood.—The red cells are usually normal in number, but there may be a slight anæmia. On the other hand, when there is much cyanosis, or after sanatorium treatment, the red cells may be increased. The colour index is usually low. In the early stages the leucocytes may be slightly increased. A polymorphonuclear leucocytosis occurs in caseation and in early cavity formation, and at times with secondary infection of the lungs. A special differential count of the polymorphonuclear leucocytes themselves may be made by subdividing them into groups, according to the number of their nuclear lobes, as suggested by Arneth. An increase in number of immature cells with only one or two nuclear lobes constitutes a deviation to the left from the normal, and raises the Arneth index. This lævo-deviation is said to indicate toxæmia, and if it is not present, the disease will probably be chronic. The von Bonsdorff modification in which the number of lobes of the nuclei in one hundred polymorphonuclear leucocytes is counted, is sometimes used. The normal figure is 274, a figure less than this suggests activity. The lymphocyte monocyte ratio is said to be of prognostic value, an absolute and relative increase in the monocytes being unfavourable.

Alimentary system.—The tongue is usually clean and the appetite good even in cases with marked fever. When tuberculosis of the larynx is present, there is frequently severe dysphagia. Dyspepsia may be complained of, usually of a nervous type. Anorexia, flatulence, distension with nausea are the commonest symptoms, pain being rarely noticed. There may be marked intolerance of fat in the diet. Atonic dilatation of the stomach may occur in some cases towards the end of the disease. Constipation is common; on the one hand, diarrhœa may occur apart from intestinal ulceration or lardaceous disease.

Nervous system.—The classical "spes phthisica" is distinctly rare, but when present is very striking from its contrast with the realities of the disease. It is most commonly seen in acute caseous tuberculosis. More often the patient becomes emotional and self-centred, depression is common and hard to combat, and melancholia with delusions occasionally develops. Neurasthenia is frequent and, as mentioned above, may lead to errors in early diagnosis. Insomnia may be due to cough, pyrexia, night sweats or pain, especially in laryngitis. With marked cachexia, a definite peripheral neuritis may occur.

Genito-urinary system.—In the early stages there is often an increased sexual desire, and this may recur when arrest is taking place. This is probably in part due to the therapeutic régime, the rest, abundant food and lack of interesting occupation reacting upon the nervous system of young adults. In advanced disease, all sexual desire is lost. Menstruation often ceases early, and the patient may seek advice for amenorrhœa. Women remain fertile even in advanced disease. The urine is normal in the early stages, later a febrile albuminuria may occur, or in advanced cases an amyloid nephrosis with generalised œdema may develop.

The Physical Signs of Early Disease.—The general appearance of the patient may be healthy, or may be that of malnutrition with the characteristics of the "habitus phthisicus," the hair being lank and lustreless, the skin white, thin, dry and shiny. and the thorax of the alar or phthinoid type. Certain stigmata are described, which although useful, are not pathognomonic. The eyelashes may be long, dark and curling, the back hairy and the thoracic cutaneous venules dilated. When present around the upper thoracic vertebral spines, they are sometimes known as "the varicose zone of alarm." Deficient movement may be observed below one clavicle, at the point of one shoulder, or at the lower costal margin. The corresponding shoulder may be slightly drooping, with flattening above or below the clavicle, and slight hollowing of the supra-spinous fossa with wasting of the trapezius muscle may be observed. Pottenger regarded these shoulder signs, when not due to scoliosis or kypho-scoliosis, as reflex, and comparable with the fixation of a tuberculous joint and wasting of its adjacent muscles. In women it may be noticed that the breast on the affected side is smaller and hangs at a lower level.

Palpation confirms the diminished expansion, and reveals a slight increase of vocal fremitus over the affected area of the lung, usually at one apex. The normal increase in fremitus of the right apex over the left must be borne in mind, in order to prevent mistakes.

With light percussion slight dullness and a small increase in the sense of resistance can be detected. This is usually most apparent in the

supra-spinous and upper interscapular regions. The extent of pulmonary resonance above the clavicle, known as "Krönig's isthmus," may be diminished by ½ to 1 inch on the affected side.

Various types of breath-sounds may be heard over the affected portion of lung. They are—(*a*) weak inspiration, with expiration vesicular or inaudible; (*b*) cog-wheel inspiration, with expiration vesicular, prolonged or rarely jerky; (*c*) the "granular" breathing of Grancher, the breath-sounds being somewhat coarse and irregular, suggesting fine or distant râles, although none can be definitely detected; (*d*) harsh inspiration, with expiration vesicular or prolonged; (*e*) broncho-vesicular breathing; (*f*) definite bronchial breathing when early consolidation is in progress.

Often there are no adventitious sounds. Occasionally a few small rhonchi or fine crackling or bubbling râles may be heard with the first few deep breaths, or only with the inspiration immediately following coughing. If râles are constantly heard, it indicates that the lesion is already of some extent. Care must be taken to differentiate them from atelectatic râles, emphysematous râles audible along the sternal margin, and pleural friction or fascial creaks. There is usually a slight increase in the conduction of both the spoken and whispered voice, and the more definitely this extends away from the trachea in front, and from the vertebral spines behind, the more reliable is the sign as an indication of disease.

Mensuration is seldom practised in routine examination, but graphic records of the chest contour, which are of interest in following the progress of a case can be obtained by cyrtometry.

Physical Signs of Acute Miliary Tuberculosis.—If the condition develops acutely from breaking down of an infected bronchial gland or small lung focus, the physical signs are generally those of an acute generalised broncho-pneumonia, unless there is meningeal involvement as well, in which case the pulmonary symptoms and signs are masked or obscured by those of the cerebral involvement. When miliary tuberculosis occurs as a terminal event in a chronic case, marked dyspnœa, cyanosis and tachycardia are early symptoms. There may be crepitations or fine crepitant râles widely distributed over both lungs, and sometimes areas of tubular breath-sounds especially in the lower lobes. The original signs are often masked or less apparent. This is especially the case if meningeal involvement occurs also.

The Physical Signs of Consolidation.—Limitation of movement and flattening over the affected part of the lung, usually the apex, is now more noticeable.

The diminution of movement is confirmed on palpation, and vocal fremitus is found to be definitely increased.

The pulmonary resonance is diminished to definite dullness and the sense of resistance is correspondingly increased.

The breath-sounds are bronchial, or in acute caseous disease may even approximate to tubular.

Adventitious sounds may be absent, but usually fine or medium crackling râles are heard with inspiration, especially after coughing. When active softening is in progress the râles frequently become coarse and sticky. The voice conduction is much increased, bronchophony and whispering pectoriloquy being audible.

Mensuration may confirm the presence of flattening.

THE PHYSICAL SIGNS OF EXCAVATION.—Flattening of the chest-wall and diminished movement over the cavity are now more marked; if the cavity is apical there is in addition notable dropping of the shoulder, and wasting of the shoulder-girdle muscles.

The diminution of movement is confirmed by palpation. Vocal fremitus is generally increased owing to the surrounding consolidation, but if the cavity is full or there is much pleural thickening, it is diminished.

The percussion note is dull when the cavity is small or filled with secretion. A peculiar boxy or "cracked-pot" note, the "bruit de pot fêlé," is obtained over large superficial cavities, especially when communicating with an open bronchus. This is best heard on percussing with the mouth open, and Wintrich showed that the note may be altered in pitch over such cavities when percussing with the mouth open or closed, apart from the actual presence of the cracked-pot sound. Gerhardt's sign (alteration of note with the position of the body) is supposed to indicate a cavity of oval shape. It is rare, and of little value.

The breath-sounds are bronchial, broncho-cavernous, cavernous or amphoric, according to the size of the cavity, and to the amount of its contents. When it is full the breath-sounds may be distant, weak or even absent, and this is especially noticeable in basal bronchiectasis.

With a dry cavity there may be no adventitious sounds. Usually râles are audible; they may be medium or large, and bubbling or crackling in character. Over a large cavity a metallic tinkle and amphoric echo may be heard. With a very large cavity, extending through the whole of one lung, a typical *bruit d'airain* is at times obtainable. Voice conduction is increased, bronchophony and whispering pectoriloquy are present, and in some instances post-tussive suction is heard. Some cavities are only revealed by X-ray examination or by tomography.

Mensuration affords a graphic representation of the flattening of the chest-wall.

THE PHYSICAL SIGNS OF FIBROSIS.—The chest is asymmetrical, the affected side being flattened and moving little, while compensatory scoliosis or kypho-scoliosis is often present. The cardiac impulse is seen to be displaced towards the affected lung and may be higher or lower than normal. It may be drawn over to the right axilla, or on the left side as far back as to the posterior axillary line, or even to the angle of the scapula. The intercostal spaces may be retracted, and dilated venules are sometimes seen over the front of the chest as the result of obstruction, caused by displacement of the mediastinum and traction on the deeper veins.

Diminution of movement is confirmed by palpation, and the cardiac impulse can be more accurately localised. Vocal fremitus may be increased or diminished; the former occurs when the lung is consolidated and the large bronchi patent, the latter when there is much pleural thickening.

The percussion note over fibroid lung is dull and the sense of resistance increased, unless cavities are present. The opposite lung may be hyper-resonant, and its resonance extend across the mid-sternal line. The cardiac dullness is often continuous with that of the fibroid lung, and its area can only be determined by the cardiac pulsation.

The breath-sounds are weak and distant, unless modified by the presence of a cavity.

Often there are no adventitious sounds, although fine or medium râles of a sticky or metallic nature may be heard. The voice conduction is usually diminished, and there is no pectoriloquy unless excavation has occurred, when bronchophony and pectoriloquy are audible.

It must be borne in mind that in actual disease the lesions are not so clear-cut and well-defined. In a case of some duration different stages of disease can be found in the same individual, thus infiltration, consolidation with softening, excavation and fibrosis may be present in different lobes of the lungs, and thus it may be possible to determine the site of origin and path of spread of the disease.

Certain other signs are occasionally seen in pulmonary tuberculosis.

Myoidema is an undue irritability of the muscles to direct mechanical stimulation, revealing itself by a flickering fibrillary contraction on tapping with the finger, and may occur in tuberculosis at all stages. It is best seen over the pectoralis major on the affected side. It may be present quite early, but is not pathognomonic, as it may occur in any cachectic state.

Clubbing of the fingers is commonly seen in chronic cases, the nails are curved and present a parrot-beak appearance, the thumb, index and middle fingers being most affected. Drum-stick clubbing is only seen in fibroid lesions with bronchiectasis.

Chronic Miliary Tuberculosis.—*Clinical features.*—Chronic miliary tuberculosis affects males and females equally. The age incidence is between 6 and 40 years, but usually the patient is between 11 and 30. The early symptoms include cough, shortness of breath, pain in the chest, expectoration and at times hæmoptysis. Constitutional disturbance is usually slight with low-grade fever. In some cases the spleen is palpable and in others tuberculous lesions are present in glands, bones or joints. Tubercle bacilli may be found in the sputum, gastric contents or pleural fluid. X-ray examination reveals small symmetrical, rather ill-defined opacities throughout the lung-fields. In some cases they may be limited to one portion of the lung. The course of the disease is more prolonged than that of miliary tuberculosis, being never less than three months and usually considerably longer. Death may occur in about six months, or eventually the disease may be arrested.

The differentiation of chronic miliary tuberculosis from the acute variety depends rather upon the clinical than the radiological findings. The fact that the pulmonary lesions are tuberculous is established in many cases by the finding of tubercle bacilli in the sputum or stomach contents. When tubercle bacilli cannot be detected, other conditions giving rise to scattered opacities throughout the lung-fields must be considered. Thus in secondary carcinomatosis, sarcomatosis or chorio-epitheliomatosis, the opacities are usually larger. Multiple opacities are also found in pneumokoniosis, congestive heart failure, sarcoidosis and more rarely with periarteritis nodosa, xanthomatosis, bilharziasis, leukæmia and disseminated broncho-pneumonia.

Hilum Tuberculosis.—The existence of a special type of pulmonary tuberculosis commencing at the root of the lungs and extending thence in a fan-shaped manner along the bronchi has been postulated by some authorities, chiefly on X-ray evidence. While lesions in the middle zone of the lung are sometimes revealed by X-ray examination, it is more than doubtful whether this condition merits recognition as a separate variety of the disease.

EPITUBERCULOSIS.—This term was applied by Eliasberg and Neuland in 1920 to a condition of consolidation in tuberculous infants, often affecting a whole lobe. In spite of definite physical signs and characteristic radiological appearances, there are few symptoms, and recovery is the rule, with fairly rapid clearing of the X-ray shadows, from the periphery inwards. It is probably due to atelectasis of a lobe in whole or part, due to bronchial obstruction from enlarged hilar glands.

HILAR FLARE is the name given by Burton Wood to a similar condition affecting the right middle lobe, or the upper part of either lower lobe in childhood. The X-ray shadow is generally triangular in shape, the base being at the hilum or mediastinum. This, like epituberculosis, is probably due in many cases to localised bronchial obstruction, but in both conditions it is possible that there may be an allergic factor.

It is important to note that in both epituberculosis and hilar flare, the chief evidence is radiological, and that the prognosis is good.

PULMONARY OSTEO-ARTHROPATHY.—In cases with bronchiectasis the joints may be affected, swelling occurring especially in the wrist, ankles and knees, and rarely in the hips and shoulders. A serous effusion into the joints may be present. Pain is usually slight, but there is much deformity and functional impairment. X-ray examination reveals productive periosteal changes, which may also affect the long bones and the spine (see p. 1376).

RADIOGRAPHY OF THE CHEST.—If possible, the chest should be examined in every case with the fluorescent screen, and a photograph taken on a film. Certain important points can only be determined by a screen examination. The chief of these are the respiratory movements of the diaphragm, lighting up of the apex of the lung with inspiration, and the cardiac pulsation. Unilateral restriction of diaphragmatic movement not infrequently occurs in early apical tuberculosis, but as it may be observed under other conditions, notably with pleural adhesions, it is not diagnostic. The film will show the extent of the disease and in some cases it may suggest the existence of activity; thus areas of consolidation, caseation or excavation can be demonstrated, and thickening of the pleura, pleural effusion and pneumothorax give their characteristic appearances. In films taken in the erect position a fluid level is often apparent in cavities. A curious rounded shadow may be apparent in early disease called Assmann's focus, in which rapid changes, such as softening, may occur. The tomograph sometimes shows unsuspected cavities.

The significance of "root shadows" is still debatable. Although the presence of calcareous deposit in the glands at the roots of the lungs is usually obvious, the interpretation of the radiating shadows is a matter still under discussion. They may be due to peribronchial thickening, caused by the formation of fibrous tissue, or may merely represent the shadows cast by the branches of the pulmonary artery.

A film is often of crucial value in determining the presence or absence of early disease, but slight diminution of translucency of one apex may be due to an old arrested lesion, or, on the other hand, there may be definite physical signs of active disease, without abnormalities being found on X-ray examination. The heart shadow is often narrow and vertical in tuberculosis. Displacement of the heart due to pulmonary fibrosis or to affections of the pleura is clearly indicated. A good film may also give valuable information as to the

extent of lung involved and as to the presence of complications, such as effusion, pneumothorax or bronchiectasis. As the X-rays only cast shadows lacking in all pictorial details, tuberculous shadows cannot always be distinguished from those due to other pulmonary lesions. It is thus clear that the X-ray findings should always be interpreted in connection with the history, symptoms and physical signs of the case. The X-rays, although often of great help, do not afford a simple road to diagnosis or supply infallible evidence in determining the nature of an obscure case. On the other hand, they are absolutely essential in the determination of the suitability of a case for artificial pneumothorax or other collapse treatment and in controlling its application.

Complications and Sequelæ.—Compensatory emphysema is common in chronic fibroid disease, but bronchiectasis occurs less frequently. Gangrene of the lung is not often observed. Colds and catarrhal affections of the respiratory passages are frequent in sufferers from tuberculosis, and lobar pneumonia may develop as a complication. Bronchitis often occurs, due either to spread of the tuberculous process or to a secondary infection. In some instances asthma appears for the first time after tuberculosis has become manifest. A tuberculous abscess occasionally forms about a rib or costal cartilage.

Small areas of dry pleurisy are present at some stage in nearly every case; a serous pleural effusion is common, and an empyema may develop as the result of a mixed infection, or from the tubercle bacillus alone. Pneumothorax may occur as an early complication, or late in the disease, generally from rupture of a caseous focus just under the pleura; this frequently progresses to the formation of a pyo-pneumothorax. The implantation of tubercle bacilli from the expired air or sputum may lead to secondary foci in the larynx, trachea and epiglottis, or more rarely in the pharynx, tonsils, base of the tongue or nose. Swallowing of sputum containing tubercle bacilli gives rise to gastro-intestinal complications in many cases. The most common site of tuberculous ulcers, is the terminal portion of the small intestine, but the appendix may be affected, and the connective tissue around the cæcum is sometimes matted and thickened to form a palpable mass (hypertrophic tuberculoma). Tuberculous peritonitis is not common in adults and is usually secondary to intestinal lesions. The stomach is very rarely ulcerated, but an atrophic gastritis may occur in advanced cases. Fistula-in-ano and ischio-rectal abscess are comparatively common complications and tubercle bacilli may be found in the discharges.

Small vegetations may be found post mortem in the heart on the aortic and mitral valves, but these are usually due to some terminal infection. Fatty degeneration of the myocardium occurs as a result of toxæmia, and infection by direct spread along the lymphatics may lead to pericarditis. The peripheral circulation is not infrequently poor, chilblains are common, and cachectic purpura may be seen. Lardaceous degeneration as a consequence of chronic tuberculosis is not so common nowadays as formerly, but when present may affect the liver, spleen, intestines, lymph glands and kidneys.

The genito-urinary complications include lesions in the kidneys, bladder, epididymis and prostate. If the suprarenal body is affected Addison's disease will usually develop. Spinal caries is occasionally observed. A peripheral neuritis may form part of the lesions occurring with marked

cachexia. Generalised dissemination of the tubercle bacilli by the blood stream is followed by tuberculous meningitis.

Course.—The course pursued by pulmonary tuberculosis is variable, depending upon the clinical type of the disease. In acute miliary tuberculosis, death may occur in from 1 to 3 weeks from toxæmia or generalisation of the lesions. In acute caseous tuberculosis, death usually results in from 1 to 6 months. In chronic fibro-caseous tuberculosis, the disease may be completely arrested, or after a temporary arrest may become active at intervals and again become arrested under suitable treatment; in other instances it progresses steadily to a fatal termination. In fibroid tuberculosis the disease may become completely arrested or smoulder quietly for many years.

Apart from the question of the expectation of life, various stages of tuberculosis are described based upon anatomical lesions, toxæmia and functional disablement. The most important of these are as follows:

1. The Turban-Gerhardt Classification.—An anatomical classification based upon the extent of lung tissue involved. Three stages are described. *Stage* 1. Early cases in which physical signs, if unilateral, only extend from the apex to the second rib, and, if bilateral, are limited to the supra-clavicular and supra-spinous regions. *Stage* 2. The signs, if unilateral, do not reach lower than the fourth rib, and, if bilateral, are situated above the second ribs. Excavation is not present in this stage. *Stage* 3. This includes more extensive lesions or localised ones in which excavation is present.

2. Sir Robert Philip's Classification.—Both the extent of lung tissue involved and the degree of toxæmia present are taken into consideration. Twelve stages are described, which are indicated by the following signs:

L_1, L_1s, L_1S, and 1_1S; L_2, L_2s, L_2S, and 1_2S; L_3, L_3s, L_3S, and 1_3S. L_1, L_2, and L_3 represent lung involvement to the extent of stages 1, 2 and 3 respectively, according to the Turban-Gerhardt scale. s applied to these letters indicates that there is only slight systemic disturbance, whereas S signifies marked systemic disturbance; and the signs 1_1S, 1_2S and 1_3S show that the systemic disturbance is excessive in relation to the lung involvement.

3. Inman's Classification.—This is based solely on the temperature in relation to exertion.

Stage 1. The patient is febrile when resting. Stage 2. The patient is resting afebrile, but ambulant febrile. Stage 3. The patient is ambulant afebrile. Stage 4. The patient is working afebrile.

The course taken by tuberculosis of the lung may lead to several terminations. These are: (1) permanent arrest, either by fibrosis prior to caseation, or if the latter has occurred, by calcification and fibrosis; (2) incomplete arrest, as shown by the persistence of tubercle bacilli in the sputum, or by slight degrees of pyrexia on over-exertion; (3) rapid extension, here the disease spreads, and the toxæmia is out of all proportion to the extent of the lesions; (4) death, this may result from the pulmonary lesion or from complications. The former may prove fatal as the result of progressive asthenia or cardiac failure, from asphyxia due to acute miliary tuberculosis or hæmoptysis, or in a small proportion of cases directly from loss of blood in repeated hæmoptysis. The complications that most often prove fatal are meningitis, enteritis, laryngitis leading to dysphagia and starvation, or

pneumothorax. Intercurrent diseases, such as pneumonia, influenza or diabetes, are occasionally the cause of death.

Diagnosis.—This is easy when definite signs are present in the lungs, and when tubercle bacilli are found in the sputum. On the other hand, the diagnosis of early cases may present one of the most difficult problems in clinical medicine. Tuberculosis may be suspected on account of symptoms, although the physical signs are indefinite. The conditions which most frequently lead to doubt are dyspepsia, neurasthenia, debility, visceroptosis and intestinal stasis, oral sepsis, tachycardia associated with early Graves's disease or heart disorders, affections of the nose and throat, and in children enlargement of the bronchial glands or acidosis. The history and symptoms are of great importance in these cases, and a careful examination should be made of each system. A test meal, opaque meal, or blood examination may be required before the correct diagnosis is established.

On the other hand, there may be definite signs of disease in the lungs which have to be differentiated from those produced by other conditions simulating tuberculosis. The cases included in this group embrace the majority of pulmonary lesions, especially chronic bronchitis, fibrosis, bronchiectasis, asthma, emphysema, apical catarrhs and collapse, pleurisy, new-growths and cysts. Diagnosis depends upon the history and course of the disease, together with a careful record of the physical signs in the chest, investigation of the sputum for infecting organisms, X-ray examination and in some cases the determination of the Wassermann reaction.

A condition of special difficulty is that of the variety of sarcoidosis known as Boeck's sarcoid. The lesion is a benign lymphogranuloma or reticulosis. It affects the lymph glands, lungs, bones especially those of the fingers, and the skin (see pp. 1478–1480). The parotid and lachrymal glands are sometimes involved and irido-cyclitis has been recorded in 10 per cent. of the cases. The intestines, spleen and liver may be affected. The chief diagnostic points are the character of the skin lesions and the chronicity and tendency to spontaneous arrest. Tubercle bacilli are not found and the Mantoux reaction is often negative. The radiological appearances in the lungs are those of a diffuse mottling—coarser than that of miliary tuberculosis. The hilar glands are often markedly enlarged.

When the diagnosis still remains doubtful the patient should be placed under observation, and a series of examinations carried out, the object of which is to determine whether or not active tuberculosis is present. The temperature should be observed with the patient in bed, a daily rise to 99° F. or a swing of 1°·5 to 2° below normal being suspicious. The sputum should be examined repeatedly for tubercle bacilli by the ordinary method, and if not found the antiformin process should be carried out.

Before applying any tuberculin tests the blood may be examined serologically. The use of the Arneth or von Bonsdorff blood count in diagnosis has been referred to on page 1196. The complement-fixation test has proved disappointing, and in the present form does not afford reliable criteria of activity or quiescence.

The sedimentation test of the blood (stability reaction), *i.e.* the rate of settling of the erythrocytes in blood diluted with sodium citrate solution, is affected in this disease. In active cases the sedimentation rate is increased, but this reaction is not specific. It is also increased in other conditions such

as pregnancy, carcinoma, syphilis, rheumatism and acute infections. The test is therefore of little or no value in diagnosis, but it affords valuable indications of the degree of activity, and may assist in determining the form of treatment.

It has also been used as a guide to prognosis, since it is affirmed that arrest should not be considered as firmly established until the sedimentation rate has returned to normal. This may not occur until some time after the usually accepted clinical symptoms and signs of activity have disappeared.

THE TUBERCULIN TESTS.—1. *Cutaneous (the Pirquet reaction).*—Scarifications are made on the skin of the forearm through a drop of Koch's old tuberculin, human and bovine, and through a drop of saline as a control. A positive reaction is shown by the formation of a slightly raised, reddened papule at the site of the scarification through one or other varieties of tuberculin, whereas the control is not affected. Unfortunately, except in the first two years of life, this affords no indication of active disease, but only reveals the presence of previous infection with resulting tuberculin sensitiveness. A positive reaction is therefore given by the majority of adults.

2. *Mantoux's intradermal test.*—An injection of 0·1 c.c. of a 1 in 10,000 dilution of old tuberculin (0·01 mgrm.) is injected intradermally. If no reaction occurs, the injection is repeated in a week, with 0·1 c.c. of 1 in 1000 dilution (0·1 mgrm.). A positive reaction is shown by a red areola, with some œdema and occasional vesiculation.

A modification of this test consists in the use of Purified Protein Derivative (P.P.D.). This is supplied in tablets of two strengths, which must be dissolved in a buffered solution immediately before use. The advantage of this preparation is its constant potency.

3. *Vollmer's patch test.*—A strip of adhesive plaster is applied over the sternum, previously cleaned with ether. To this strip are attached three small squares of filter paper, the central one is a control of untreated paper, the other two have been saturated with undiluted old tuberculin and allowed to dry. The plaster is removed in 48 hours and 12 or 24 hours later a positive reaction is shown by redness, infiltration and sometimes by papules or vesicles.

4. *The subcutaneous test.*—The patient must be apyrexial, and must be kept in bed—$\frac{1}{10}$ mgrm. of old tuberculin is injected subcutaneously, and its effect determined. The reactions that may develop are—(*a*) local, an inflammatory swelling at the side of the injection; (*b*) focal, an increase of the signs observed at the seat of disease in the lungs, such as the temporary appearance of a few râles at one apex. This is the most important; (*c*) general, as judged by a rise of temperature and sense of malaise. The temperature should be charted 4-hourly after the injection, and a rise to over 99° F. indicates a positive reaction. If no reaction follows this initial dose, larger injections are given at intervals of 2 or 3 days, in this sequence: $\frac{1}{5}$, $\frac{1}{3}$, 1, 5 and even 10 mgrms.

This test has the drawback that it does not indicate activity of disease, and it has the additional disadvantage that it may cause a quiescent pulmonary focus to light up and spread, and so cause irreparable damage.

Finally, the X-rays afford most valuable assistance in the diagnosis of early cases with doubtful signs, and also help in the differential diagnosis of tuberculosis from other lung diseases with well-marked signs.

Prognosis.—A number of factors must be critically considered in the determination of the prognosis in pulmonary tuberculosis.

A marked family incidence generally suggests an unfavourable course, though this rule is not invariable.

Personal history.—Chronic alcoholism is serious, chiefly because the régime of treatment is then peculiarly irksome, while the digestion and powers of resistance are often impaired in alcoholics. Tuberculosis in syphilitics frequently assumes a fibrotic type, and its course may be beneficially influenced by anti-syphilitic treatment. The outlook is grave when tuberculosis is conjoined with diabetes though less so since the use of insulin. Congenital heart disease and pulmonary stenosis are unfavourable factors; but hypertrophy of the heart and mitral stenosis are said to be beneficial.

The prognosis is very grave in infants and young children; but slightly less serious up to the age of 20. Between 20 and 50 age has little influence; but in later years the outlook becomes progressively less favourable.

Apart from the effects of pregnancy and exposure, sex plays no important part.

Freedom from financial embarrassment improves the prognosis, inasmuch as advice can be sought early, and treatment carried through thoroughly.

Marriage often leads to a breakdown in arrested cases especially in women, and induces more rapid spread of active lesions.

Persistence in an unfavourable occupation, or return to it after completion of institutional treatment, affects the prognosis adversely.

Poor chest development and the "habitus phthisicus" are usually bad prognostic signs, although tuberculosis may run a rapid course even in patients with good physique.

Patients with resolute and persistent personality are more likely to persevere with treatment and to recover, than those of weaker moral fibre.

The prognosis is greatly affected by the type of the disease—acute miliary tuberculosis is usually rapidly fatal, whereas in acute caseous tuberculosis, although the prognosis is very grave, recovery may occur. In fibro-caseous tuberculosis the prognosis is most uncertain and difficult to forecast. Every factor must be carefully considered, and the response to treatment noted. The best outlook is in fibroid disease, which often undergoes complete and permanent arrest.

Symptoms in their Relation to Prognosis.—Persistent cough, by exhausting the patient and disturbing sleep, is often unfavourable.

The amount of sputum is usually dependent upon the type of disease and upon the presence of secondary infection, and may therefore be of value in prognosis.

The significance of tubercle bacilli in the sputum.—The figures obtained at the Midhurst Sanatorium, over a period of 8 years, in which the after-history of the patients was traced for the ensuing 6 years, show that the prognosis is best in "closed" cases; but that it is nearly as good in those cases in which the tubercle bacilli disappear from the sputum during the sanatorium treatment. Persistence of bacilli in the sputum is an unfavourable sign. The actual number of bacilli in the sputum and the presence of "beading" have no definite prognostic significance.

Cases commencing with hæmoptysis progress more satisfactorily than

those with other modes of onset, chiefly because they are diagnosed earlier. Hæmoptysis occurring later may exert an unfavourable influence, either indirectly by spreading the disease into previously healthy portions of the lungs, or actually by the loss of blood.

If dyspnœa is not due to attacks of bronchial spasm, it has usually an unfavourable significance.

The temperature affords a clue to the type and activity of the disease, and is thus a valuable aid to prognosis. Profuse and persistent night sweats, or marked anorexia, especially when occurring early in the disease, are grave signs. Tachycardia due to toxæmia, signs of cardiac failure, œdema and albuminuria are of bad omen. The blood pressure is thought by some to be a useful guide, systolic figures below 100 mm. Hg being unfavourable, whereas a rise of pressure may be associated with amelioration of the disease. In fibroid lesions the pressure may be raised throughout.

The Extent of Physical Signs.—The activity of the disease rather than its extent is the important factor in determining prognosis. The development of compensatory emphysema is of value only as an indication of fibrosis in the tuberculous portion of lung, and therefore of chronicity.

The Influence of Complications on Prognosis.—Generally speaking, the presence of complications increases the gravity of the disease. Involvement of the larynx is a serious complication, especially when accompanied by dysphagia; but complete recovery may take place if the pulmonary lesion is quiescent. In early cases spontaneous pneumothorax occasionally acts favourably; but when it develops in association with extensive tuberculosis, and especially if it progresses to pyo-pneumothorax, it is almost invariably fatal though, if the disease is unilateral, surgical measures may prove successful.

Pleural effusion often has a beneficial influence by diminishing the movements of a lung in which there is an early tuberculous focus.

Secondary catarrhal affections tend to increase the cough and expectoration, and may lead to further spread of the disease.

Meningitis is almost invariably fatal. Tuberculous peritonitis or enteritis is a very grave complication, but fistula-in-ano often occurs in chronic cases, and exerts no marked deleterious effect. Involvement of the genito-urinary system increases the severity of the disease, especially if the kidneys or bladder are affected. If the epididymis alone is involved the prognosis is not materially affected, as the lesion can be dealt with surgically, although the administration of a general anæsthetic may cause spread of the pulmonary disease. For this reason when operations are urgently needed on these patients, gas and oxygen, basal anæsthetics, local or spinal anæsthesia should be insisted on.

As shown by the figures obtained at the Midhurst Sanatorium, a fairly accurate guide to prognosis is afforded by observing the condition of the patient on admission to the sanatorium, and his response to treatment. Even in the most favourable cases, which are diagnosed in an early stage, and progress satisfactorily under treatment, the mortality rate is six times greater after discharge from the sanatorium than it is for the remainder of the population of England and Wales for the same age periods; whereas in the cases of advanced disease the mortality rate is thirty-eight times greater than for the average population. As the most critical time is during the two

or three years succeeding discharge from the sanatorium, the prognosis is largely affected by the conditions of life during this period.

The rate of sedimentation of the erythrocytes (see p. 1204) has proved to be a valuable aid to prognosis. A persistently rapid rate is unfavourable.

Treatment.—PROPHYLACTIC.—The prophylaxis of tuberculosis involves a consideration of public health questions dealing with the purity of the milk supply, the infection of meat, sanitation and housing, the early diagnosis of tuberculosis, the examination of contacts, and the segregation of "open" cases. Inoculation with the B.C.G. vaccine (attenuated living bovine bacilli) has not met with favour in this country. All these questions are considered in the general article on Tuberculosis.

CURATIVE.—This varies with the type and stage of the disease. In all acute or febrile cases treatment should be commenced at home or in a nursing home or hospital, where the patient can be under careful observation in bed. The various forms of treatment which may be considered are—(1) sanatorium treatment; (2) home or institutional treatment; (3) dietetic treatment and personal hygiene; (4) climatic treatment; (5) graduated rest, exercise and labour; (6) medicinal treatment; (7) specific measures; (8) operative treatment; (9) symptomatic treatment.

1. SANATORIUM TREATMENT.—This constitutes the best mode of treatment for early and for certain types of chronic disease; but is totally unsuited for acute febrile or very active cases. The advantages obtained are: (*a*) the patient learns the most suitable mode of life, and the methods employed to check the spread of the disease; (*b*) the housing is specially designed and the climatic conditions are good; (*c*) the dietary is abundant and adapted to the patient's needs; (*d*) there is constant skilled medical supervision, and the daily routine is adapted to the actual physical condition of the patient.

On arrival a newcomer is kept in bed for a few days in order that his resting temperature may be observed, and the necessary examinations carried out. If there is pyrexia, rest in bed must be enforced until the temperature falls to normal. If the temperature rises above 99° F. when the patient is up, return to bed is usually necessary. The routine of sanatorium treatment varies in different institutions, the most important divergence being whether or not a system of "graduated exercise" is employed. In nearly all an hour's recumbent rest is enforced before lunch and dinner.

After three months' stay it is usually possible to decide whether the patient is responding to treatment, and, if so, it should, if possible, be prolonged for at least another three months, or until the sputum is free from tubercle bacilli.

2. HOME AND INSTITUTIONAL TREATMENT.—Treatment at home, in nursing homes or in special hospitals, is essential in early cases with fever, and in cases in which it is necessary to establish the diagnosis. Home treatment is also usually necessary on return from sanatorium or climatic treatment, if arrest is incomplete. An endeavour should always be made to carry out the principles inculcated at the sanatorium, and the patient should be under regular medical supervision. Advanced cases are best looked after in special institutions.

3. DIETETIC TREATMENT AND PERSONAL HYGIENE.—It is desirable to graduate the diet in each case so that the patient is restored to the previous maximum weight; but, in order to accomplish this, the food should be slowly

increased and all ideas of enforced overfeeding discountenanced. A total calorie value of 3000 to 3500 is usually ample; but, if the patient is performing heavy work, as much as 4000 may be necessary. Meat, fish, eggs and fats are usually well tolerated. It is not often necessary to give large quantities of milk when the patient is on a full dietary. If extra food is required, the protein may be increased by raw meat sandwiches. Additional carbohydrates with small daily doses of insulin if they are not well tolerated are often helpful.

In all cases in which there is expectoration the patient should be clean-shaven. Great care must be taken in the disposal of sputum to ensure that it does not become dry, and that flies do not have access to it. All patients who are up should carry special sputum flasks, while those who are in bed should have sputum cups suitably covered and containing disinfectant. The sputum should be burnt, or, if this is impossible, it should be emptied into the water-closet after disinfection with carbolic acid or other simple or cheap disinfectant.

Smoking is best avoided in cases of active disease or laryngeal tuberculosis, and in no instance should inhaling be allowed. Woollen under-garments should be worn; but all excess of clothing is harmful. Sun-bathing and injudicious uncontrolled sun exposure are dangerous and often activate quiescent lesions. Patients should be strongly warned of this danger.

4. Climatic Treatment.—This is undoubtedly of value in carefully selected cases. The climatic resorts fall into three groups—mountain, marine and inland.

The mountain resorts.—In Europe the most suitable places are found in Switzerland. Among these are St. Moritz (6090 feet), Arosa (6000 feet), Davos (5150 feet), Montana (5000 feet) and Leysin (4690 feet). In America the most celebrated resorts are in the Rocky Mountains at Colorado Springs (5000 feet) and Denver (5000 feet), or in the Andes or Adirondack Mountains. The advantages of high altitudes consist in the stillness, purity and rarefaction of the air, and the greater diathermancy of the atmosphere to the sun's rays. Metabolism and the general circulation are thereby increased.

High altitudes are suitable for early cases which are afebrile, or for quiescent cases of more advanced type. Contra-indications are recent hæmoptysis, active disease with fever, extensive fibrotic lesions and complications such as emphysema, asthma, cardio-vascular lesions or nephritis.

Marine and coast resorts.—Among the important coast resorts in the British Isles are Hastings, Bournemouth, the Isle of Wight, Torquay, Falmouth, Llandudno, Penmaenmawr, Scarborough, Mundesley and the various seaside towns in Thanet. Farther afield are the French and Italian Riviera, Madeira, the Canary Isles, Morocco, Algiers and Egypt. The climate tends to be warm, moist and equable, and the amount of ozone is probably increased. These resorts are especially suitable for cases of more advanced and active disease, and for those complicated by hæmoptysis, bronchitis, emphysema and laryngitis. Residence by the sea actually at sea-level is undesirable.

Inland resorts.—These are to be found on the English and Scottish moorlands. The climate of California, the South African veldt, and parts of Australia and New Zealand are admirably suited to this disease, especially for arrested or early uncomplicated cases; but the laws against the admission of tuberculous patients are strictly enforced at all of them.

Sea voyages.—These are contra-indicated for all except completely arrested

cases owing to the lack of fresh air in cabins, the possibility of sea-sickness, and the difficulty of obtaining suitable treatment if the disease advances.

5. GRADUATED REST AND EXERCISE.—Treatment in bed is necessary so long as there is fever, and if the raised temperature is persistent "absolute rest" should be enforced. This consists in keeping the patient recumbent in bed, sufficiently well covered to prevent any muscular contraction from chill, while feeding and washing are attended to by the nurse, and the use of the bed-pan and slipper for evacuations is insisted upon. When the temperature becomes normal the patient is allowed up for varying periods, commencing with 1 hour daily, and increasing slowly to 6 or 8. If still apyrexial, walking exercise of 1 or 2 miles or more daily can be allowed.

The system of "graduated exercise" which Paterson instituted at the Frimley Sanatorium has proved of great value. There are six grades, the first and lightest consisting of walking up a slope carrying a light weight such as a basket of earth, while the sixth and heaviest involves hard manual labour with a pickaxe or shovel for 6 hours daily. This system is based on the principle that muscular exercise leads to the discharge of tubercle toxins from the pulmonary focus, and by liberating these in gradually increasing doses, a condition of active immunity is induced. A careful watch must be kept during this controlled process of auto-inoculation to prevent excessive doses of toxin being discharged, which are early indicated by rise of temperature and of pulse-rate, headache, increased cough and expectoration, lassitude and malaise. If such occur, the patient should be put back to bed for a few days, and when the condition has subsided the graduated exercise may be resumed at the grade which induced the over-inoculation or that immediately below it.

6. MEDICINAL TREATMENT.—No specific drug has yet been discovered for the treatment of tuberculosis. Amongst the medicines in most general use are:

(*a*) *Cod-liver oil.*—This may be administered by the mouth in doses up to 2 ounces daily. The cod-liver oil may be of value either on account of its fat-soluble A and D vitamins content, or, as suggested by Rogers, it may assist by dissolving the capsules of the tubercle bacilli and so facilitating their disintegration. Halibut liver oil is now sometimes used instead.

(*b*) *Creosote.*—This may be given in doses of min. 2 to 3 three times a day after food, either in combination with cod-liver oil, or in capsules. It should be discontinued if gastric disturbance or hæmoptysis ensue.

(*c*) *Hypophosphites.*—These are not so generally used as formerly and, beyond their "tonic" effect upon the nervous system, have no demonstrable influence upon the pulmonary lesion.

(*d*) "*Nascent*" *iodine.*—With the idea of liberating free iodine in the tissues, potassium iodide grs. 30 is administered after breakfast in half a pint of water, and throughout the day 3 to 5 ounces of chlorine water are consumed with lemonade. This treatment is of value in certain chronic fibroid cases, but it often produces no appreciable results, and may cause dyspepsia.

(*e*) *Arsenic.*—Liquor arsenicalis min. 2 to 3 by mouth, or sodium cacodylate gr. $\frac{1}{4}$ to $\frac{1}{2}$ subcutaneously, are of value in some cases associated with anæmia. Neoarsphenamine, administered intravenously, is useful in chronic cases complicated by syphilis.

(*f*) *Inhalations.*—Disinfectant drugs when inhaled often check cough lessen expectoration and improve the general condition of the patient. Lees's inhalation is of value. It consists of creosote, parts 2; acid. carbol., 2; liq. iodi mitis, 1; sp. ætheris, 1; and sp. chlorof., 2. About 6 drops an hour are placed upon a Burney-Yeo mask, which should be worn almost continuously throughout the day. A modification now more frequently employed is: menthol, 4; olei cinnamomi, 3; olei limonis, 4; creosote, 10; olei pini, 10; sp. chlorof., 10.

(*g*) Calcium is often given by the mouth in the form of colloidal calcium in doses of 60 minims three times a day; or intramuscularly, as calcium gluconate, 5 c.c. of a 10 per cent. solution once or twice a week. Parathyroid extract is sometimes administered at the same time.

(*h*) There has been a revival of interest in preparations of gold in the treatment of this disease, notably by Møllgaard, who uses sodium aurothiosulphate, to which the name of sanocrysin has been applied. It is now administered in smaller doses than when it was first introduced. The initial dose is usually 0·01 g. dissolved in sterile saline solution and injected intravenously. The second dose is given 5 days later, and is as a rule 0·025 g. If no reaction occur, the dose is increased to 0·1 g., and usually later to 0·25 g., the intervals being extended to a week. The total amount given in a course is usually 3 g., or sometimes up to 5. The course may have to be interrupted owing to reactions, chiefly fever, albuminuria, stomatitis, diarrhœa, peripheral neuritis and skin manifestations.

7. Specific Measures.—(*a*) *Active immunisation.*—Tuberculin and tubercle-vaccines.

The tuberculin treatment has not fulfilled the high hopes held out on its introduction by Koch. There are now numerous forms of tuberculin available, indicated by certain letters, and falling into three groups. (1) Those containing the exo-toxins only. These include Koch's old tuberculin T., O.T., and T.O.A., Denys' bouillon filtré (B.F.) and albumose-free tuberculin, T.A.F. (2) Those containing the endo-toxins chiefly, such as Koch's "new" tuberculin, T.R. (3) Mixtures of endo- and exo-toxins, the most important of which are Koch's bacillary emulsion, B.E., the sensitised bacillary emulsion, S.B.E. and Béraneck's tuberculin, T.Bk.

The Therapeutic Substances Act, 1925, restricts the term "tuberculin" to the first of these groups, and recommends the name "tubercle vaccine" for any substance obtained directly from the bacterial bodies.

Tuberculins and tubercle-vaccines may be prepared from human or bovine bacilli; if from the latter the letter P. (perlsucht) placed before the letters indicating the variety of tuberculin, signifies its origin, *e.g.* P.T. In administration, some aim at producing reactions and establishing tuberculin tolerance by giving large doses at fairly frequent intervals; others believe in minute doses at longer periods, the chief object being to avoid the production of any reaction. The actual doses are either measured in milligrammes of dried tubercle bacilli, or in cubic centimetres or cubic millimetres of the fluid tuberculin. The usual method is to measure the doses in cubic centimetres or fractions thereof, and to make the necessary dilutions in a series of bottles. Smaller initial doses should be used with a strong tuberculin such as the B.E. than with the weaker ones such as the T. or T.A.F. Thus, if adopting minute doses, $\frac{1}{500,000}$ mgrm. of B.E. would be a suitable initial dose, then for T.R.

$\frac{1}{100,000}$ mgrm. would be used and $\frac{1}{1000}$ mgrm. of T., B.F., or T.A.F. As the different tuberculins are supplied by the makers in varying strengths, 0·001 c.mm. of the original fluid is equivalent to the above doses.

Those who believe in minute doses commence with 0·001 c.mm. and work up to 0·1 c.c., whereas others commence with 0·5 to 1 c.mm. and increase to 1 c.c. The tuberculin should be injected subcutaneously, and a careful observation kept for local, focal and general reactions. Tuberculin, if used injudiciously, can be productive of harm. At Midhurst Sanatorium it was tried for some years, and no better ultimate results were obtained than in the "non-tuberculin" years. It seems wise, therefore, to use tuberculin only in very carefully selected cases, thus T.R. does at times appear beneficial in chronic tuberculosis, promoting the formation of fibrous tissue and leading to the disappearance of tubercle bacilli from the sputum.

Various attempts have been made to remove as far as possible the fatty and waxy constituents from the tubercle bacilli before preparing a vaccine from it. Much and his collaborators have employed partial antigens or partigens derived from tubercle bacilli, singly or in varying combinations. Some good results are on record from both of these methods, but on the whole their use has so far been disappointing.

Grasset has recently recorded success with a preparation described as "tubercle endotoxoid," which he claims is freed from the toxic factor in ordinary tuberculins.

(*b*) *Passive immunisation.*—The various serums such as those prepared by Marmorek and Maragliano have not proved successful, and this applies to the "contra-toxin" of Mehnarto and the "I.K." (immune bodies) of Spengler.

8. Operative Treatment.—(*a*) *Artificial pneumothorax.*—This mode of treatment is now becoming more generally adopted in selected cases. It is increasingly employed in cases of early disease, where there are indications of incipient softening or of recent cavitation. In early cases without softening it is not as a rule used, unless there are indications of rapid spread or of pleural involvement when it is wise to start before adhesions have formed. In extensive bilateral disease it may be dangerous. If old and dense pleural adhesions are present, it is impracticable. If there is much emphysema or cardiac embarrassment, it involves risk. It is also of value in certain cases of repeated severe hæmoptysis. Tuberculous laryngitis or enteritis are not contra-indications, providing that other conditions are suitable. Sterile air is introduced into the pleural cavity, and the lung allowed to collapse. The method of induction of artificial pneumothorax is as follows: A preliminary subcutaneous injection of $\frac{1}{3}$ grain of papaveretum (omnopon) is given half an hour before the start. The patient lies on the sound side with the head low and supported on a pillow. A second pillow is placed under the chest to expand the intercostal spaces. The skin and the tissues down to the pleura are anæsthetised with 2 per cent. procaine hydrochloride solution after the application of iodine. The site usually chosen is in the sixth intercostal space in the mid-axillary region. A special pneumothorax needle, attached by a rubber tube to the pneumothorax apparatus, which is carefully examined to see that it is in proper working order, is then pushed through the intercostal space until the pleural cavity is reached. The apparatus is then adjusted so that the intrapleural pressure can be observed. No air should be introduced until the manometer shows a normal negative

pressure range with inspiration, of 5 to 10 or more cm. of water. This is the test of entry into the pleural space, and when this is established 200 to 300 c.c. of sterile air may be allowed to enter the pleural cavity. The final pressures are then recorded and the needle is withdrawn. A refill is given next day and another after two more days, the quantities of air introduced being determined by the final pressures, which should be kept slightly negative. Subsequent refills are gradually spaced out to a week, then ten days and later to two, three and four weeks' intervals. The usual custom now is to maintain the collapse for three years or even longer. If the condition of the patient is satisfactory, re-expansion may then be permitted cautiously. It should be remembered that after expansion pleural adhesion almost invariably occurs and the treatment by artificial pneumothorax cannot be repeated. In some cases of bilateral disease, which is active but not very extensive in either lung, a cautious use of bilateral artificial pneumothorax has proved practicable and helpful, but very great care is necessary in adjusting the pressures.

There are certain dangers in the procedure. These are now rare, and they can usually be prevented by careful attention to the technique. Death has occurred from pleural shock when the needle has reached the pleura and before any air has been introduced. Adequate anæsthesia of the pleura is the only known method of eliminating or minimising this risk. If the lung is adherent to the chest-wall, owing to pleural adhesions, or if the needle is pushed in too far, it may be inserted into the lung or into a pulmonary cavity; the manometer will then show a swing above and below the zero line instead of entirely below it. Under these circumstances, no air should be allowed to enter. The needle may be inserted into a blood vessel. In this case the manometer pressure will rise above zero, and blood may appear in the glass section inserted in the rubber tube leading from the manometer to the needle. The needle should be withdrawn immediately, lest air should enter the vessel.

If the pleura is found to be adherent at the site of the first puncture, another attempt may be made elsewhere, *e.g.* just below the inferior angle of the scapula. This spot may be selected for the initial puncture in left-sided cases where there is marked cardiac displacement. In cases in which localised band or cord adhesions prevent adequate collapse, it is often possible to cut them by electrocautery or diathermy through an operating thoracoscope, thus ensuring completely effective collapse. This is called internal pneumolysis.

(*b*) *Oleothorax.*—Sterilised olive oil or liquid paraffin with a varying percentage of gomenol is sometimes used to maintain the collapse started by artificial pneumothorax. Paraffin is used when the mediastinum is unduly mobile, since it tends to thicken the pleura. The oil or paraffin is introduced by means of a Dieulafoy syringe, and air is withdrawn at the same time by a reversed artificial pneumothorax apparatus. Whichever is used, it is important to test the sensitiveness of the pleura by small injections of 2 to 5 c.c. to start with. In later injections the amount introduced may be gradually increased to 200 c.c. or more. Oleothorax is now for the most part restricted to cases of therapeutic pneumothorax tending to obliterate from spreading adhesion, and those with mobile mediastinum.

(*c*) *Evulsion or crushing of the phrenic nerve.*—This is now often performed

in order to produce basal collapse, but it helps to produce relaxation at the apex and may aid in the contraction and closure of a cavity. Division alone is not sufficient; it is desirable to remove as long a stretch of the nerve as possible. In recent years temporary paralysis has been induced by crushing the nerve, the effects lasting about 6 months. This is often carried out instead of evulsion, since it does not prejudice further surgical treatment subsequently.

(*d*) *Thoracoplasty.*—If owing to adhesions it is impossible to collapse the lung temporarily by an artificial pneumothorax, permanent collapse by thoracoplasty may be considered. In the Sauerbruch operation, the posterior 3 or 4 inches of the ribs from the first downwards are removed, even to the tenth or eleventh, the lower level being determined by the extent of the compression of the lung it is desired to produce and therefore by the amount and situation of the diseased area. This operation is now performed in two or three stages, and generally under local anæsthesia. Good lateral collapse is usually obtained by this operation, but antero-posterior compression is less complete. Semb's operation is more satisfactory and is now more frequently employed. The first, second and third ribs are completely removed and the fascial supports of the apex of the lung are divided, which is thus allowed to sink down, producing a concentric collapse. The second and if necessary a third stage are similar to those in the Sauerbruch operation.

(*e*) *Apicolysis* (*extrapleural pneumolysis*).—Successful local collapse can sometimes be attained by introducing some extraneous material like paraffin between the chest wall and the parietal pleura over a local area of disease, or a cavity which is not too near the pleura.
